POINTS FOR PRODUCERS.

Bureau Congress.

Considerable interest is being evinced among the Branches of the Agricultural Bureau in the forthcoming Congress to be held in Adelaide from September 8th to 10th inclusive. The proposed banquet on the evening of September 8th to celebrate the silver jubilee year has met with general approval, and delegates and other members are securing tickets daily. Early application is necessary to obtain these, as arrangements with the caterers must be made some little time before the date. Full particulars may be obtained from the Secretary to the Advisory Board of Agriculture, Adelaide. His Excellency the Governor and the Minister of Agriculture will be present and deliver addresses. The opportunity will be taken to present the Certificates of Life Membership to members of the Bureau.

Conference of Hills Branches, Agricultural Bureau.

The Annual Conference of the Hills Branches of the Agricultural Bureau will be held at Mount Barker on October 13th. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.) has been invited to open the Conference, and the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), the Horticultural Instructor (Mr. Quinn), and the Government Veterinary Lecturer (Mr. F. E. Place) have been requested to address the Conference. Practical papers will be read by delegates from some of the Hills Branches of the Bureau.

British Exports of Live Stock.

In a booklet issued by the British Board of Agriculture relating to the exportation of live stock from the United Kingdom, it is shown that far and away the greatest trade is done in horses. During 1911 (the latest figures available) about 19,000 horses were exported from British farms and studs at excellent prices. The Argentine bought 269 British-bred horses at an average price of £178 each, for instance, while the 13 that went to Sweden averaged £250 each. On the whole, the hackney would appear to be the most of the demanded breeds, and, with the hunter, make up the majority of the exported horses. The best exported cattle go to the Argentine to improve the great beef herds. During 1911 the Argentine bought 243 head for £20,910, while, as a contrast, Austria-Hungary bought 551 for £9,476. The United States, the largest customer, bought 772 for £25,209.

Black-Nosed Cattle.

Everybody knows, writes the *Agricultural Gazette*, that the old wild white breeds of cattle, such as the Chillingham, had black muzzles, and though breeds had been improved from them, the black muzzle remained, until the general improvement of the last century so gradually established breeds vastly better, and in course of time the black nose, as indicating the older type, was bred and weeded out. Yet there are plenty of farmers living who remember when they had to cull the black-nosed cattle and speckled-face sheep from lots they bought, because they knew that they were really unimproved and that they were bound to be unprofitable. To-day the same thing merely indicates a cross between recognised breeds, and all that is necessary is to be able to recognise what those breeds are, and to buy or refuse them as they think they are suitable for the purposes to which they will be put.

A Maize Experiment.

The East Anglian Institute of Agriculture, at Chelmsford, in 1912, held some experiments with maize. The following varieties were tested :—White Cap Yellow Dent, Longfellow, Angel of Midnight, Quebec Yellow, Champion White Pearl, Improved Leaming, Eureka, Wood's Northern Dent, White Horse Tooth, Giant Caragua. The first eight were Canadian and American seed. The last two were purchased at Reading. The maize was ploughed in on May 16th. The seed was sown at the rate of 2bush. per acre, and in rows 20in. apart. A dressing of 10 tons dung, 1cwt. nitrate of soda, 3cwts. superphosphate, and ½cwt. sulphate of potash per acre was given. The following conclusions were reached :—(1) Many of the above varieties are capable of producing a very heavy weight of fodder per acre. The yield, as compared with 1911, showed a great increase, which was attributed to heavier rainfall and to better tilth. (2) The first five varieties are fairly equal in cropping capacity, and did well both in 1911 and 1912. (3) In 1911 Improved Leaming, Wood's Northern Dent, and Eureka gave the best yields, and they cropped well in 1912 also. (4) The superiority of the Canadian and American seed in 1911 was not maintained in 1912. (5) It is important to cut maize at the right time. This seems to be just before the male flower fully appears from the sheath. Sutton's Early Prolific was sown with the rows at 24in., 20in., 16in., and 8in. apart respectively. The experiment showed that (1) the largest crop is obtained from the narrowest rows, and (2) that rows at 20in. apart are much more profitable than at 24in. It is pointed out, however, that in making rows closer than 20in. other factors must be considered, namely, the large amount of seed required, and the difficulty of horse-hoeing, which is very important in a dry season.—*Agricultural Gazette.*

South America as a Market for Apples.

The June number of *The Fruit World of Australasia* contains an interview taken from a New Zealand daily with Mr. Thomas Horton, of the firm of Messrs Thomas Horton, Limited, nurserymen, of the Dominion, in regard to the market for fruit in the Argentine. Mr. Horton paid a visit to the Argentine for the purpose of inquiring into the subject, and as a result he declares that there is practically an unlimited market there for fruit. "One firm," he states, "gave me a definite order for 200,000 cases of apples, to be shipped each year for five years during the months of March, April, May, and June, and stipulated that if we were unable to supply that quantity during the next few years we were to send every case that we could possibly muster if we could supply them at 6s. 6d. per case, f.o.b." The varieties of apples said to be in greatest favor with the Argentine importers are Jonathan, Cox's Orange Pippin, Scarlet Nonpariel, Rome Beauty, Cleopatra, Dunn's Favorite, Ben Davis, Rokewood, and Reinette du Canada.

Adaptability of Breeds.

In selecting a dairy breed it is not a matter of which is the best breed, but the one best suited for prevailing conditions. Select with a view to adaptability and for the purpose for which the animal is kept. Some breeds are noted for the quantity of milk they produce, others for the richness of their milk, others for the color of cream or butter. All these things must be taken into consideration before selecting a breed. Of the dairy breeds the Holstein has a number of high producing animals. They point with pride to such animals as Colantha 4th Johanna, with a record of over 1,100lbs. of butter in the year, and the late queen of the dairy world, Banastine Belle De Kol, with a record of over 1,300lbs. of butter in 365 days. The Jersey has Jacoba Irene, the Guernsey Dolly Dimple, and the Ayrshire Netherhall Brownie, all of which were a credit to their respective breeds.—*American Agriculturist.*

Methods with Potatoes in Russia.

Depth of planting potatoes appeared to make little difference, in some Russian tests, as the yields following planting to depths of 1¼in. to 5¼in. were almost equal. The four-year average yield secured from planting the transverse halves was somewhat greater than the three-year average secured by the use of the longitudinal halves. Both were excelled by the four-year average resulting from the use of whole tubers. In dry years the yield from the halves was considerably lower than that secured by the use of whole tubers, but in wet years the reverse was the case. In the dry year of 1909 the making of hills proved injurious, but in the wet year of 1908 it appeared advantageous. Planting potatoes 14in. apart in tests at the Uman Agricultural School were practically equal to those secured by planting 17½in. apart each way during a five-year period, and somewhat greater than those secured by planting 21½in. apart each way during six years or 28in. during four years. In wet years planting 21in. apart each way was followed by the higher yields, while in dry years 14in. apart each way appeared the best distance. In the rather wet year of 1908 potatoes planted 21in. apart each way on ridges gave lower yields than those planted in furrows, but the usual method of planting gave considerably better results than the use of either furrows or ridges. In the dry year, 1909, however, the best yields were obtained by planting on ridges.

Marketing Farm Produce.

The most important item in marketing is to present produce in attractive form and in an attractive package. Purchasers have no way of judging the quality of the goods except by appearance, and often an inferior article tastefully presented will meet with a more ready sale than a superior article poorly presented, simply because it is more attractive to the eye. The seller must have a good reputation before buyers will be on the lookout for him and his produce.

Keep Time on the Dairy Herd.

Factories and big offices use a time clock which registers the minute each employé comes in, and again when he leaves. Thus there is no guesswork about the hours put in, and each receives the proper amount of pay for his work. Can you think what it would mean, says *The American Agriculturist* if you could keep track of the work your dairy cows do in some such way ? If one was a shirk you could fire her out, and if one did extra good work you could give her more feed. If you kept this up for a generation or two, saving the good ones and getting rid of the poor ones, your herd would improve, wouldn't it ? And after awhile you could have it so that every animal was working full time and paying the proper sort of profit. Successful dairymen everywhere are doing that very thing. Instead of a clock it is a pair of scales. They are adjusted to just balance an empty pail, so the milk reads direct, without any subtraction. A ruled sheet with a column for each cow is tacked on the wall near by, and a pencil is handy. It takes but a moment to drop the bucket on the hook, mark down the weight, and be gone again. At the end of the month, and again at the end of the year, it stands there in black and white. Why don't you try that way of improving the stock ? Don't do it if you mean to sell out in a year or two ; it's too much trouble. But if you are in the business to stay and make good, buy a pair of spring scales and a penny lead pencil, borrow a sheet of paper, and start in.

Why Fertilisers Failed.

"Many farmers expect entirely too much of commercial fertilisers," says an authority. "They forget that the physical condition of the soil is often just as important as the supply of available plant food. The condition of the soil depends largely upon the amount of decaying organic matter it contains. By it clay soils are kept loose and well aerated, are more easily drained, and at the same time capable of holding more water in an available form. They have less tendency to surface washing, heaving, and extremes of temperature when well supplied with organic matter. Sandy soils are made more compact, more retentive of moisture and plant food. In all soils the acids produced by the decay of organic matter are the chief agents in getting into usable form the plant food locked up in their insoluble mineral particles. If disappointing results attend the use of fertilisers, it is well for the farmer to ask himself if he has made sufficient use of barnyard manure, heavy sods and green manuring crops, in maintaining the supply of organic matter of the soil."

New Experiments on the Fertilsing Property of Sulphur.

Experiments, states the June number of *The Fruit World*, have been made to ascertain whether flowers of sulphur have any effect on the growth of barley and rye. The experiments were carried out in the experiment garden of the Agricultural Institute at Nancy, in a very rich clay soil after beets. The soil analyses gave an average sulphuric acid content of 0·082 per cent. It is well known that most soils are poor in sulphuric acid, the amount varying, according to Hart & Petersen, from 0·033 per cent. to 0·14 per cent., almost always remaining below 0·10 per cent. The sulphuric acid present in the experimental soil was thus an average amount. The sulphur was applied before sowing (at about ¼oz. per square yard, or 90lbs. per acre). The sowing was done on February 25th, 1912. The favorable effect of the sulphur showed itself from the beginning in the stronger growth and brighter green of the plants on the treated plots. This result persisted till the crops ripened. The crop reaped on July 26th was weighed (grain and straw together). The average weight per plot of 2 sq. m. (2·4 sq. yds.) was as follows :—

	Barley.	Rye.
	lbs.	lbs.
Without sulphur	13·0	9·5
With sulphur	16·5	12·75
Increase due to sulphur	3·5	3·25

These figures clearly show the good effect of sulphur upon the cereals used for the experiment.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Government Veterinary Lecturer.)

The Mangalo Branch inquire the cause of a young calf, two days, losing use of its legs, eyes turning white, shivers; calf seemed in good health. Another calf sucked mother cow before her own was born.

Reply—The symptoms are altogether too indefinite to venture an opinion on, but it is possible that the animal's heart had not undergone the changes which occur at birth.

"G.B.S.," Dunira recently bought a cow supposed to be in calf, which has a discharge of blood from the bearing about every three weeks. He asks for advice.

Reply—The symptoms described suit several diseases of the generative system, and there is a risk that in your case the cow is suffering from contagious abortion, and has already slipped her calf, so that it would be well to let a veterinary surgeon examine her. In the meantime isolate her from the rest of the herd, and syringe her out with a pint of warm water containing 1 L.G.B. Soloid B. & W., and repeat three times at three-day intervals. Also give her once as a drench ¾lb. Epsom salts and 1oz. ginger in a quart of warm beer. Follow this with 10 drops of veterinary tincture of pulsatilla daily for a week.

"M.," Stockport, has found that after castration with the emasculator by different men there is a swelling of the purse which is permanent. He asks for advice.

Reply—The emasculator is not to blame. A sufficiently large cut was not made in the outer skin, and the wound healed too quickly so that the discharges were retained in the inner skin, making a "wind stone," or the colts were cut too proud, as the inquirer says, "only half castrated." This was the case in the one which did not swell for two years. The instrument is often blamed for the operator's work. It has made the operation so easy that every farmer can do it for himself if he will only cut a very large hole in both outer and inner skins and cut the cord above the pride.

"Bletchley" reports that a young cow was killed after a few days illness which resembled lockjaw without the closing of the jaws. The bible was large and hard.

Reply.—It is usual to find the bible at third stomach large and hard, both in health and disease. Probably water was as scarce as feed was said to be, and the illness was caused by the absorption of poisonous residue from the feed, so-called "dry bible." Three pounds oats and 6lbs. chaff daily is starvation ration for a cow giving 2½galls. of milk a day.

The Arthurton Branch asks for advice concerning a mare which for the last three months frequently almost goes down, stamps, and bites on flank; worms are feared.

Reply.—Worms, bots, and internal abscesses all produce the symptoms mentioned, and probably all three help to cause the trouble in this case; while sand is also very probably present also. Treat for bots first; after a few days give a course of Fowler's solution for worms, as so frequently recommended lately, but do not be surprised if one day the mare goes down finally with a ruptured bowel caused by accumulations in the large gut. This is a case requiring the personal examination of a qualified veterinary surgeon before the real cause of the symptoms can be stated.

HORTICULTURE.

"H.B.," Beetaloo Valley, inquires regarding growing cherries in his district.

Reply.—The Horticultural Instructor (Mr. G. Quinn) writes in reply—*Re* cherries.—If you have a number of varieties which bloom simultaneously and still no fruits result, I would feel pretty well certain the non-productive character of your trees could be attributed to unsuitability of general soil and climatic conditions. Truly, the cherry is only a real success in South Australia over a very limited range of country in the Mount Lofty hills, and, personally, I do not think they will ever pay you to grow in the North, even if you obtained a shilling per pound for the fruits. I know of no stone fruit for which the cherry affords a suitable stock on which to graft. If you root them up, open a good hole, and plant pears or some fruit trees quite dissimilar to a stone fruit. *Re* Beurre Clairgeau pears falling.—This is a characteristic failing of this otherwise valuable variety. Fortunately in this case, although I cannot suggest how to keep the fruits on a tree of Beurre Clairgeau, you can graft the trees over to better varieties without a long delay preceding the reproductive period. I suggest you put on as grafts, Beurre Bosc, Madame Cole, or Packham's Triumph.

A Stirling West resident asks for information regarding "black spot" disease in walnuts and "bitter pit" in apples.

Reply.—The Horticultural Instructor writes—*Walnut Disease.*—The walnut disease causing defects in the nuts throughout the Mount Lofty Ranges is known as bacteriosis of the walnut. It is due to a bacterium. As far as is known no spray remedy is effective, as the germ, by methods not yet discovered, enters the sap, and is then out of reach of external dressings. All I can suggest is to gather all diseased fruits from the trees or ground from time to time and burn them. The disease also affects at times the terminal points of the young shoots. These turn pale and show distinct evidences of the effect of the germ in withered leaves, &c. Such points should be cut off and burnt. By following these precautions for a couple of seasons you have a chance of reducing the attack. *Bitter Pit.*—Bitter pit is a disease of the apple and pear fruits, which is not caused by any organism, but appears to arise through disorganisation of the sap flow and tissues fed thereby. It appears to be aggravated by heavy winter pruning, more especially by cutting back the leading shoots. I would advise light pruning and only thinning out lateral shoots the winter before you expect a heavy crop. Do not overwater or stimulate the trees with manure and allow the branches to take a pendulous rather than erect form.

"M.V.," Clarence Park, asks for advice concerning the non-setting of almonds on his Brandis trees.

Reply.—Mr. Quinn states—The Brandis almond is not a good bearer. I think this is due to the following facts :—(1) It blooms too early in spring to escape bad weather, and no other almond is blossoming with it to permit proper cross fertilisation of the blossoms. (2) Its foliage and fruits form just at the time when the shothole fungus is very active, and in consequence suffer much from the attack of this disease. The remedy for non-setting may consist in growing hardshells, or some early blooming sort, such as Peerless, with the Brandis ; and the shothole may be lessened by spraying the trees with Bordeaux mixture, made by dissolving 1lb. of bluestone in 5galls. of water and slaking 1lb. of fresh quicklime in 5galls. of water, and then blending the two together.

POULTRY.

(Replies supplied by Mr. D. F. LAURIE, Poultry Expert.)

"W. P. E." inquires the cause of some incubator-hatched chickens being cripples.

Reply.—Cripples occur as a rule through lack of moisture in the machine at time of hatching. You should test your thermometer. Borrow from a chemist a clinical thermometer and compare readings.

"J. R. D.," Mile End, is desirous of learning how to distinguish cockerels from pullets in the case of newly-hatched chickens.

Reply.—There are three points which distinguish the cockerel from the pullet in newly-hatched chickens, and if you note these you will make but few mistakes. They are as follows in order of value :—(1) Examine the vent and blow lightly. If a pullet, the sphincter muscles will contract several times, but rarely in the cockerel. (2) The comb on newly-hatched chickens is nearly always erect on the cockerels and lying flat on one side on the pullets. (3) The spur bud on the cockerel is large and more conspicuous than on the pullet in most strains.

"J. G. R." asks the temperature at which incubators should be worked, and also what added moisture is required ?

Reply.—You do not say what incubator you are using, so that I have nothing to guide me in my reply to your question. Instead of damping the eggs I should recommend you to dip a sponge, or a bit of flannel or old blanket, the size of the egg tray, dip it in hot water, squeeze it out, and spread it over the eggs. Do this two days before the eggs are due. It is important for you to be quite certain that the thermometer is correct.

"P. E." requires information as to the construction of poultry yards and houses.

Reply.—A yard 3ft. wide and 12ft. long will afford ample space for one male bird. At the end of the house there should be a small yard, and you should put plenty of straw and scratching material on the ground. For a yard 18ft. x 30ft. build a shed 18ft. long, 6ft. wide, with a division in the centre, so as to make two houses in each ; and then you can put 10 to 13 laying hens. Let them out on alternate days into the yard which occupies the remainder of the space. You should use jarrah posts, oregon rails, and galvanized iron for shed, and wire netting 6in. in the ground and 6ft. 6in. out of the ground. To get this you will require 4ft. and 3ft. netting. Your best plan for egg production is to build a house as I have described and yard for each of them 9ft. wide, the same width as the house, and 40ft. long ; 30ft. will do, but it is rather short.

SOME LOCAL ECTO-PARASITES OF POULTRY.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

[Paper read before the Microscopical Section of the Royal Society of South Australia, May 27th, 1913.]

Following on my researches into the life history of the poultry tick (*A. Persicus*), the results of which were read before members of this society and published in Bulletin No. 74, it will be of great interest to poultry breeders to describe and illustrate other external or ecto-parasites which affect poultry and are found in this State. It is not my purpose to write either a history, or to make an attempt to classify and refer to all the species hitherto discovered here. I will content myself with a description and some account of the habits of such as are common, and of which I have collected specimens.

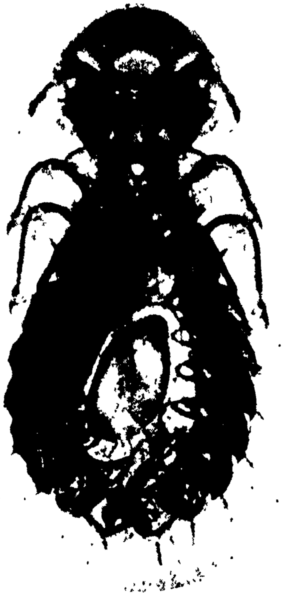

PLATE I.—*Goniocotes Gigas*, Taschenberg.
FEMALE, VENTRAL. X 26.

Quite apart from the fact that infested birds and poultry houses are attributable to great carelessness and neglect upon the part of the poultry keeper, there is the important consideration of the damage done and the frequent losses which occur and are due to ecto-parasites. Poultry which are infected by parasites (vermin) are prone to disease, because they become weak through loss of blood in some cases, and through the effects of irritation in other cases. The more recent view is that we must regard external parasites with grave suspicion as likely carriers and distributors of disease organisms. This is known to be the case in many instances, notably the poultry tick, which acts as carrier and distributor of a micro-organism, the spirochæte, responsible for the so-called poultry tick fever or spirochætosis.

Head of Male, *vide* Plate I. × 74

An Erroneous Idea.

Some people labor under the erroneous idea that it is right and proper for all animals to harbor parasites. Many have the idea that parasites "breed," that is to say that they come from nothing, or perhaps from dirt—what is known, in fact, as spontaneous generation. This idea is quite wrong, and the idea of spontaneous generation was long ago exploded. Poultry which are infested with parasites have become infested by the parasite in the first case, or through an egg. A bird whose skin and feathers had been effectively sterilised would remain free of vermin for all time if kept under such conditions that infection from outside sources could be prevented.

The study of parasites and parasitism is becoming a very important one, and in all parts of the world scientific investigators are at work, studying the structure, habits, and general life history of the different species and subspecies.

The present work will relate to the animal parasites—lice, mites, &c. At some future time the vegetable external parasites, generally microscopic, will be referred to. The animal parasites, generally termed mites and lice by breeders, belong to the group *Arthropoda*, or jointed-limbed animals. They are again divided into the *Acarina* (mites) and the *Mallophaga* (lice).

The lice are true insects, but in a degraded form through the loss of wings. They live upon the skin, devouring its debris, and often causing lesions or sores. Others live upon the feathers, and sometimes cause a more unsightly appearance on the birds. The lice live permanently on the poultry, only leaving the body after death of the host, or, as most poultry men know, when the host—the infested bird—is handled. Mites and poultry fleas are only partial parasites, as they do not as a rule live on their host, but pay visits for the purpose of blood-sucking, &c. As a rule poultry lice are easily exterminated, and in this respect are not comparable with poultry tick. Dipping in any of the sheep dips, kerosine emulsion, and in numerous proprietary dips of which there are legion, is a cheap and effectual method of dealing with this pest, as, in addition to the parasites, their eggs also are destroyed. The most important point to observe is that all methods must be thorough. If birds are infested they must be dipped, and at the same time the poultry houses and roosting places generally must be thoroughly cleansed, and by the application of suitable agents the vermin and their eggs must be destroyed. It is futile to expect to eradicate vermin by methods commonly adopted, such as throwing about a few pounds of lime or a handful or two of sulphur, or by a half-hearted application of a little weak spray of some insecticide. In addition to vigorous measures, the provision of dust baths is to be commended. These should be under cover, and may consist of fine road dust, to which may be added wood ashes and a little sulphur. The fowls will, as a rule, frequently resort to these dust baths, and to rid themselves of the pests, which are smothered and destroyed by the fine dust. Some fowls do not avail themselves of the dust bath, and this is especially the case with male birds. At regular intervals the birds should be examined, and if infested in the slightest degree prompt measure should be adopted. When this advice is universally put into practice there will be far less heard of many diseases which at present cause great loss.

The general technical term *Phthiriasis* has been given to skin affections caused by lice. Poultry lice belong to the suborder of *Hemipterous* parasites. Neumann says, " These are small-sized (only a few millimetres in length), apterous insects, of a dull-white color, and the mouth of which is adapted either for pricking or masticating. The head bears two simple eyes, or *ocelli* (often but little distinct), and two antennæ, composed of three, four, or five articles. The three thoracic segments are more or less confounded with each other. The abdomen is generally composed of nine segments. The legs are ordinarily short and strong. The tarsi are formed of two articles, the last of which has two nails, or hooklets, by which the insect can creep. The eggs, called nits, are pyriform, have an operculum at one end, and are fixed very solidly to the hairs or feathers by a glutinous substance. The young, which leave the egg by the operculum, have quite the shape of the adults, and do not undergo any metamorphoses, though they only acquire their definitive color and consistency after several moultings.

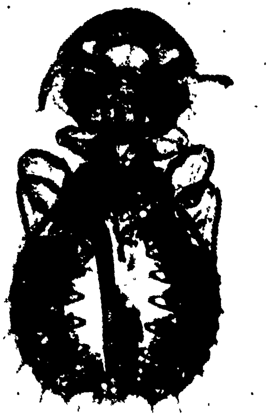

PLATE III.—*Goniocotes Gigas*, Taschenberg.

MALE, DORSAL VIEW. × 26.

MALE AND FEMALE.

The male and female differ from each other in the former being a little smaller than the latter, frequently by peculiarities in the antennæ, by the last abdominal segment being divided in the female and rounded on the male, which has also, on the middle line, a copulative apparatus of a brownish color, and are digitiform or lancet shaped. The males are usually much less numerous than the females.

Of the Hemipterous parasites there are two families, the Pediculidæ and the Ricinidæ. With the latter, or Mallophaga, we have now to deal. These have the buccal apparatus formed for mastication ; they are pellivorous in the matter of feeding, and live on the epidermic (skin) productions or upon the feathers (pennivorous). The pieces constituting the mouth are placed at the inferior (lower) surface of the head. The tarsi (end of legs) terminate in one or two claws. These mallophaga do not suck the blood, and are in some respects commensals as far as the scurf-eating species are concerned. The Ricinidæ, or Mallophaga, are divided into two subfamilies. The Philopterinæ, which have the antennæ composed of three or five articles, and have no maxillary palps, and two (the Liotheinæ) whose antennæ have four articles, and are provided with quadri-articulated maxillary palps projecting beyond the anterior border of the head. The Philopterinæ are divided into 11 genera, but of these only five are parasitic on birds, viz., Ornithobius, Lipeurus, Goniodes, Goniocotes, and Docophorus.

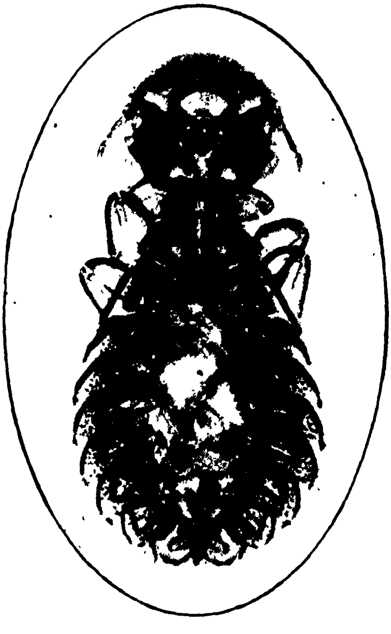

PLATE IV.—*Goniocotes Gigas*, Taschenberg.
FEMALE, DORSAL VIEW. × 26.

The Liotheinæ comprise 10 genera, of which the following are parasitic on birds, viz., Trinotons, Colpocephales, and the Menopons. As these are probably all in this State, they will each in turn be briefly referred to as the occasion arises.

COLLECTING SPECIMENS.

It will help the work of collecting information about local parasites if readers will kindly forward specimens to me for identification. The easiest method of procedure is to put a little ordinary methylated spirits in a bottle ; if a chemist is at hand, ask for the addition of a few drops of sulphuric ether. Take a small camel hair pencil, or a feather dipped in spirits and touch the parasite. This either kills or stupifies it, and it may then be transferred to the little bottle. Particulars of locality, and the kind of bird (fowl, duck, goose, turkey) on which it was found, and also, if possible, the part of the body should be given.

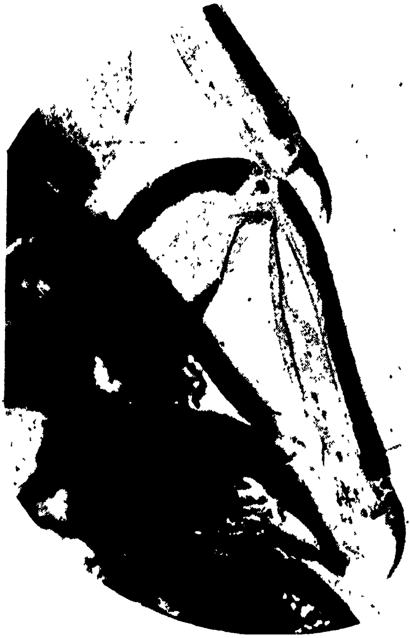

PLATE V.—*Goniocotes Gigas*, Taschenberg.
CLAWS, *vide* Plate I × 103.

The specimens are prepared by me and then mounted in xylol balsam on glass slips, and after identification are photographed by means of a Zeiss micro-photographic camera. By this means one gets a very greatly magnified picture of a parasite, so that the details of structure can be readily seen and understood.

Goniocotes Gigas, Taschenberg.

This belongs to the subfamily Philopterinæ, family Ricinidæ, suborder Phthiriases ; host, the domestic fowl.

This is the largest of the species of the Goniocotes, and is recognisable by its round and very large abdomen, as well as by its great size. The general color is light-yellow, the abdomen and metothorax are brighter colored, and the bands and outline of the spots are dark. The female is 4mm. and the male 3mm. long. The specimens here illustrated were whitish on the back, and the characteristic curved markings are almost black. This species is pellivorous, that is, it lives on the epidermis. Theobold records it as not very common in England, and that he has not seen it on the fowl. Neumann describes it and figures it. In the United States of America Department of Agriculture bulletin on Insects Affecting Domestic Animals it is mentioned, but the distinctive "gigas" is given as a synonym for *abdominalis*. Piaget. Curiously enough, the authors of the bulletin write, "It is the form commonly referred to in English and American works as *Goniocotes hologaster* which doubtless accounts for its not having been described until quite recently." Either this is quite wrong or else both Neumann and Theobold are wrong; these world-famed authorities figure "hologaster," which is a most markedly distinct species.

The species is not common in South Australia, and it is only during recent years that I have seen many specimens. The first collected came from some of the competition fowls sent to Roseworthy Poultry Station. They were collected by the Superintendent, and until I had time to properly identify them were variously classed by those who saw them as the duck louse (*Docophorus icterodes*), which they somewhat resemble at first glanc ; and others again said the pig louse (*Hæmatopinus urius*, Nitsch or *H. Suis*, Linn., which they certainly do not resemble. Later on other specimens came from various parts of the North. As a rule they were found on the feathers, stationary, and proved very slow in their movements. In bottles on feathers they lived only a few days, and died apparently of starvation.

The series of micro-photograph are from my own balsam mounts, and in each case there is considerable magnification. Any good insect powder dusted among the feathers will speedily destroy these insects. Dipping, as previously advised, may also be resorted to. So far I have no specimens of eggs of *Goniocotes gigas*.

DESCRIPTION OF PLATES (PHOTO.-MICROGRAPHS).

From original preparations made and photographed by the author.

Plate No. 1 shows a large female *Goniocotes gigas*, viewed ventrally (from the under side). Four of the six legs are shown slightly extended ; the third pair is only partly visible. The bristles on various parts of the parasite are also clearly depicted. Shows a characteristic rounding of the posterior portion of the body, and also the first articles of the antennæ, which are longer on the male than on the female. The strong legs and claws are well shown.

Plate No. 2 shows a much enlarged view of the head, and gives details of the antennæ, mouth parts, bristles, and portion of thorax. This is the head of parasite shown in plate 1.

Plate No. 3. A dorsal (looking down on the back or upper surface) view of the male *Goniocotes gigas*.

Plate No. 4 shows another female, dorsal view, slightly smaller than that shown in plate 1. This illustration well depicts the characteristic body markings of the species. Upper articles of limbs, the antennæ, bristles, and mouth parts are also clearly shown.

Plate No. 5. This plate shows a highly magnified view of the claws of the specimens shown in plate 1. Portions of the second and third pair of legs are seen, showing tarsi and hooklets. In the upper claw are seen the two articles, one of which is movable.

(To be continued.)

River Murray Reclamation Works.

BACTERIAL DISEASE OF POTATOES.

By T. G. B. Osborn, M.Sc., Professor of Botany, Adelaide University.

Specimens of potatoes infected with a bacterial disease having been received from Mount Compass, the following note has been written to give further information on the subject:—

Rotting of potatoes owing to the agency of bacteria of various species commonly follows such diseases as Irish blight when the infected tubers are stored. In the case of such a rot the bacteria are not the prime cause, but merely act as scavengers, destroying the tissues already attacked by other fungi. There are, however, at least two important diseases of potatoes which may be definitely ascribed to the action of bacteria infecting the growing plants.

Bacteria are simply-organised plants of very minute size. They act mainly as destroying agents, bringing about the destruction of waste animal and vegetable matter. A large number of species live in the soil, a cubic inch of which may contain many millions, and there they fulfil most useful functions. On the other hand, many species are parasitic upon animals, being very harmful to man, producing such diseases as diphtheria, typhoid, &c. In the last few years several species have been recognised as causing diseases of plants. Among the more important of these are *Bacillus amylovorus*, causing pear blight in the United States of America, but not yet recorded out of America, and *Pseudomonas campestris*, causing rot of turnips, cabbages, and other cruciferous plants. This latter occurs in the market gardens around Adelaide, and growers would do well to realise in time its serious possibilities as a destroyer of the various cruciferous crops, and burn infected plants rather than allow them to rot on the ground, so reinfecting it.

Of the two more important bacterial diseases of the potato, one, that known as "black-leg" or "black stalk-rot," has not as yet been brought to my notice in South Australia. McAlpine (1) records it in Victoria, but apparently in most seasons it is not common. In Europe it is much more serious; in Germany at times as much as 75 per cent. of the crop may be destroyed by it. The second disease is that recorded from Mount Compass, produced by *Bacillus solanacearum*, and is popularly known as "bacterial rot" or 'bacteriosis." McAlpine (2) records a number of popular names by which it is known in Victoria, of which "sore eyes" appears very expressive, as the eyes of the potato in the early stages of the rot are moist and the soil has a tendency to cling to them.

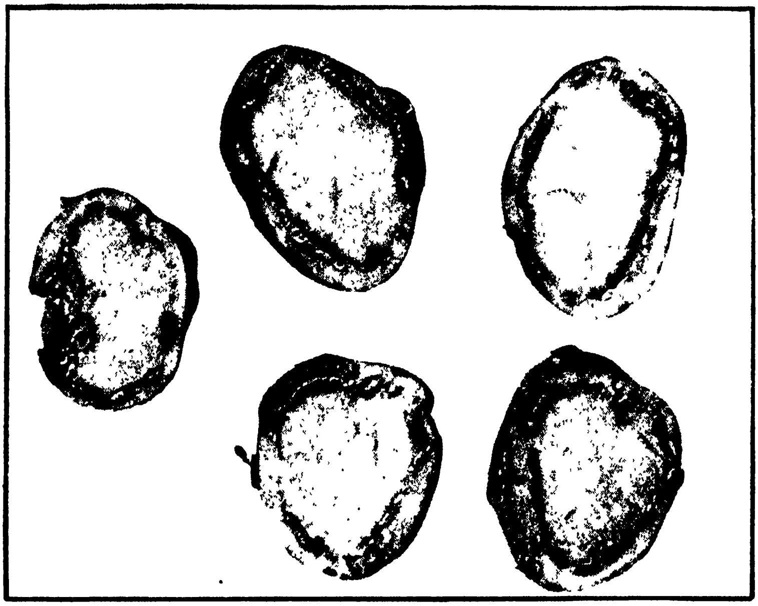
---

(1) McAlpine. D: Potato Diseases in Australia, 1911, p. 90.

(2) McAlpine, loc. cit., p. 87.

Appearance of the Disease.—The first sign of infection is stated to be a wilting and shrivelling of the leaves of the young potato plant. This is followed by a browning of the stem as the attack proceeds down the woody parts of the plant to the tubers.

In case of a slight attack, however, the disease is not usually observed by the grower until the crop is lifted. Then, in some of the tubers, a softening of the eyes is noticed. They appear moist and, as previously stated, the soil has a tendency to cling to them. If at this stage the tuber be cut across, there will be noticed an irregular brown ring about ¼in. below the skin following the position of the veins in the tuber. (See figure.) The bacteria are in these, and a turbid, greyish slime may be noticed exuding from their cut ends. The slime consists of countless numbers of bacteria.



Sections across potatoes infected with bacterial rot. Notice the discolored ring, in which can be seen white areas. These are slime masses, containing bacteria, that ooze from the cut ends of the veins. The section on the left has been cut in the region of an eye and shows an extension of the rot involving the flesh of the tuber. One-third natural size.

The rot proceeds, becoming most marked at the eyes and heel end of the potato. In a few days the whole tuber will be rotten, the flesh turning to a whitish-grey slime, which has an objectionable smell. It is often noticed that potatoes apparently sound when lifted rot shortly after.

Parasite.—The bacterium is a little rod-shaped organism. Like all bacteria it multiplies exceedingly rapidly by dividing into half. Each half divides again, and so on. By this process of division a single bacterium dividing once each half-hour may give rise to several millions at the end of a day.

Bacteria vary in their power of living in the presence of fresh air. The organism producing potato bacteriosis is aerobic, that is it needs a supply of fresh air, and this may account for the more rapid way rotting proceeds after the crop is lifted.

Cycle of Disease.—The leaves and stem of the plant are usually first infected. In some cases, though, infection appears to be due to bacteria present in the soil directly attacking the tuber. Dr. Smith (3) considers that rapid spread of the disease may be due to leaf cutting and punching insects feeding first on infected and then on healthy plants. The bacteria multiply in the wood vessels of the stem, thence by means of the underground stems into the tubers. The rot soon spreads from the veins until the whole of the tuber is involved. On the break up of the rotten potato the bacteria are scattered in the soil. It is probable that they can live there for some length of time. The disease is reported as sporadic in its occurrence in South Australia. Where it occurs the effects are most marked on damper parts of the field ; hence it is not surprising to find it largely on reclaimed swamp land.

Prevention.—It cannot be too clearly stated that in dealing with bacterial diseases the question is entirely one of *prevention.* As far as is known at present, no method of curing infected plants is possible where a bacterial disease exists in an annual crop. The growers' efforts can only be directed towards limiting the spread and preventing a recurrent outbreak.

1. All infected plants should be removed and burned as soon as they are observed.

2. Diseased potatoes and the tops of infected plants should on no account be left to decay on the land. This only saves up trouble for the future by keeping the disease in the soil. Diseased portions should always be burnt.

3. Potatoes should never be planted in infected soil. It is reported that the disease may occur on the same land after several years.

4. Care should be exercised to obtain clean seed, and no tuber showing a brown ring when cut should be used.

5. Drainage and spraying both indirectly help to reduce the amount of the disease, since the dampest spots are the most affected, and by spraying, the leaf-puncturing insects are kept in check.

DISEASES OF FARM ANIMALS.

RESPIRATORY DISEASES OF CATTLE—*continued.*

By R. H. F. MACINDOE, L.V.Sc., Assistant Veterinary Surgeon, Stock Department.

(*Continued from page* 1367.)

PLEURISY.

This is an inflammation of the lining of the chest cavity, which also envelopes the lungs. As a rule it is rarely found as a distinct disease, but is generally a complication accompanying pneumonia.

Predisposing Causes.—Exposure to cold or wet, blows, fractures of ribs, &c.

Symptoms.—In first stages great pain is shown on moving, the animal is usually stiff, and the breathing is abdominal, being usually accompanied by a short grunt. The chest is fixed so far as possible, the indrawn breath is short and jerky, and elbows turned out. The pain is due to the friction of the dry inflamed pleural surfaces of the lung and chest on each other. Pressure between the ribs causes the animal to flinch and grunt. Muzzle hot and dry, temperature 104° to 106° F. In a few days the temperature falls to 103° F., pain decreases, stiffness disappears, and the patient eats a little. Gradually the animal loses strength. The latter symptoms are brought about by internal changes taking place, the dry condition of the lining membrane having undergone a change and become moist. Now, if one lays an ear against the chest wall, gurgling sounds are heard every time the animal breathes, and by tapping the chest with the fingers he will get horizontal lines of dullness according to the amount of fluid present. As the disease progresses the animal shows a haggard appearance, and the eyes appear to be sunken. Unfavorable cases end in death in from 10 to 21 days.

Treatment.—The same general care is required as recommended for bronchitis. Combat the fever by giving sweet spirits of nitre, 1oz., concentrated solution of acetate of ammonia, 1oz., in half a pint of water two or three times a day. When fluid is forming in the chest, apply strong mustard paste to chest walls, and the following can be given internally three times a day, viz., tincture digitalis, 1oz., potassium iodide, ½ dram. Sometimes fluid is removed from chest cavity to relieve the heavy breathing, but would not recommend the layman to attempt it.

Pneumonia.

This is an inflammation of the lung itself. There are three forms, but as they can only be distinguished one from the other by the practitioner, I will treat the subject under the one heading.

Causes.—Bacterial mainly, but the disease may also be brought on by careless drenching, parasites, and may also follow an attack of bronchitis.

Symptoms.—Usually the disease is ushered in by a chill, which may not always be observed by the attendant. An elevation of temperature is observed, usually 105° to 107°. The breathing is quick and shallow, nostrils dilated. Cough may be present, nose dry, tongue may be slimy. Urine is usually high-colored and scanty, and bowels constipated. On tapping the sides of thorax with fingers, the sounds are practically normal at this stage. In the second stage the temperature generally drops a few degrees, and breathing is very difficult. Cough is frequent and painful. Animal stands with forelegs wide apart and elbows turned outward. If lying down, the animal rests on brisket. Milk secretion is suspended. Extremities hot and cold alternately. On sounding the chest wall by tapping, dull areas are found, showing consolidated areas in lung. In the third stage if the disease is going to terminate favorably the cough becomes looser, the animal's appetite returns, and all symptoms gradually subside. In fatal cases the breath becomes fetid and is taken in gasps, the extremities become clammy and cold, and death takes place.

Treatment.—The animal must be placed in clean, healthy surroundings and carefully nursed. The probability of recovery depends largely on the area of lung involved, as well as the degree of inflammation present. In early stages when fever is high give sweet spirits of nitre and solution of acetate of ammonia in same doses as prescribed for pleurisy. If bowels are constipated give calomel, 1 dram to 3 drams. In second stage diffusible stimulants are indicated, such as the following :—Spirits of sweet nitre, 2ozs.; aromatic spirits of ammonia, 1oz. ; mix, and give in gruel three times a day ; or an alcoholic stimulant such as brandy or whisky in half-pint doses may be given three times a day. Rub on the chest walls such medicaments as mustard or turpentine, ammonia liniments.

DISEASES FOLLOWING PARTURITION (CALVING).

Retention of Afterbirth.

The cow is especially liable to this accident, partly on account of the peculiar connection between the womb and the fetal membranes, the fetal membranes being attached to the walls of the womb by buttonlike processes called "cotyledons."

Causes.—Low condition of health, imperfect power of contraction. Sometimes a temporary retention is caused by a too rapid closure of neck of womb after calving, which causes a strangulation or imprisonment of the membranes.

Symptoms.—As a rule the membranes can be seen hanging from the passage, but in other cases the membranes are not seen; but animal is noticed to strain frequently, and there is a passage of fluid varying in consistency according to the state of retained membranes, and generally a strong fetid smell. Tail becomes matted with the material. At first the temperature may be normal, but gradually it rises to 103° to 104°; animal goes off her milk, muzzle dry, and animal shows general uneasiness.

Treatment.—Before recommending lines of treatment it is necessary for the owner or attendant to understand that absolute cleanliness is essential, not only in regard to their own persons, but also the same rule applies to utensils, water, &c., used. The animal should be placed in clean surroundings. If the retention is due to insufficient contractible power of womb due to weakness of animal, contraction may be brought about by giving warm gruels, hot mashes, &c., without any medicines being required. A simple purgative drench may be given, containing 1lb. Epsom salts with ½lb. of treacle in a quart of lukewarm water. The removal of membranes by mechanical means is, however, often called for, and there are many methods of so doing.

A common practice among cattleowners is to tie stones, bricks, horseshoes, pieces of wood, &c., to the protruding membranes in order to get them away; but this method is to be condemned, not only on grounds of unsightliness, but also on account of the danger of causing an eversion of the womb itself, and also that the membranes may be in a gangrenous state, and by this indiscriminate dragging apart may break away and a part may be left in womb. There is another method often used, in which the dependant part of the afterbirth is caught between two sticks and then rolled until it lies against the passage, and by careful traction accompanied by slight jerking movement the womb is stimulated to contract and expels the membrane, which in turn is again wound around the sticks until the whole of membrane is delivered. But this method has the same objection as with the first, on account of liability of membrane breaking.

The best method is to remove the afterbirth by hand. First clean hands and arms thoroughly, smear with carbolised oil or some such similar preparation, and, whilst an assistant holds tail out of the way, the operator should hold afterbirth in left hand and insert the right hand in womb, and pass it along until it reaches the points of attachment of the membrane, when gentle traction must be exerted and the afterbirth comes away freely from the passage. After the operation is completed, irrigate the womb with a warm solution of Condy's fluid, which serves to allay any irritation and acts as a disinfectant. The strength of Condy's solution is gauged by the color, which should be of a violet tinge. Keep the animal quiet, and put on good diet, but not too much grain.

METRITIS (Inflammation of Womb).

The degree of inflammation varies, it may be slight or violent, simple, or associated with putrefaction of its liquid contents and general poisoning.

Causes.—Bruising and laceration during difficult calving, infection by retained afterbirth, and also infection by introduction of attendant's arm which has not been thoroughly washed and cleaned before so doing; also exposure to cold and wet.

Symptoms.—Generally appears from one to three days after calving, when the animal may be noticed to shiver, hair along spine is rough and staring, and the horns, ears, and limbs are cold. Temperature 103° F to 104° F., appetite is lost, milk diminished, and breathing hurried. Hind limbs may shift uneasily, tail is switched from side to side, head and eyes turned to right flank, and a grinding of teeth is heard. Pressure on right flank causes pain, shown by moaning or grunting. The womb appears inflamed, and may be swollen, and there may be a blood-tinged discharge, which later may become thick and yellow. Some cases recover quickly, may be well again in a couple of days, but a large number perish within 48 hours, whilst other cases may gradually recover, taking a fortnight to three weeks. In the worst cases there is local septic infection and ulceration, and there may be gangrene of the parts, and in other cases inflammation of veins of womb, which causes a clotting of blood in them, and a small portion of clot may become detached and find its way to heart or lungs, in the latter case causing pneumonia.

Treatment.—In the slight cases, where there is only a simple inflammation, washing out the womb with warm solutions of carbolic acid and water, using a teaspoonful of carbolic acid to the quart of water or solution of alum and water, two tablespoonfuls of alum to pint of water, will often be found to be efficacious. In severer cases wash out the passage with warm water to which Condy's crystals (½oz. to 2pts. of water) and 1oz. each of glycerine and laudanum has been added, which makes an antiseptic and soothing douche. It is usually desirable to keep the bowels open by giving Glauber's salts (8ozs. in 2pts. of water) with little treacle and 1oz. ginger.

In the very septic cases, *i.e.*, those cases which have a high temperature and yellow-colored fetid discharge, give besides the foregoing such agents as quinine 2 drams, salicylate of soda ½oz., or hyposulphite of soda 1oz. every four hours. If temperature should rise as high as 106° or 107°, apply cold water to body. The animal may be covered by wet sheets and water poured on until temperature per rectum (anus) is 102°. If in winter, will have to rub animal dry and rug.

In septic cases the attendants must for their own protection be very particular as to state of hands and arms, seeing they are free from cuts and sores, are clean, and protected before being passed into womb by applying an oil containing some disinfectant, such as carbolic acid, lysol, &c.

MILK FEVER.

This disease is fairly common, and usually occurs 24 to 48 hours after calving, though cases have been known to occur up to three weeks after, and is manifested by a sudden loss of consciousness and a general condition of paralysis.

Cause.—The actual cause unknown.

Predisposing Factors.—There are many conditions which favor this disease, such as age of the cow, most animals being affected generally between the age of 5 and 10 years old. The condition of animal plays an important part, inasmuch that animals in gross condition, good doers, and heavy milkers are very prone to the disease. The kind of food and mode of feeding it is another important factor. Well-nourished cows which are being liberally fed as the time for calving approaches, especially with green fodder, are very liable to the disease. This disease is only found in connection with calving, and never before the establishment of milk secretion. Cows which have had difficulty at time of calving are seldom attacked.

Symptoms.—The first symptom noticed is the animal is off food, is restless, and now and then emits a dull bellow. Then a weakness may be noticed in hind quarters, by the animal being inclined to trip and knuckle over at fetlocks, and finally tumbling to ground. As a rule, however, the symptoms the attendant first notices is that the animal is down, with head turned to the left flank and unconscious, or may be the animal is lying on its side. When the attendant approaches and examines the animal, he notices that the eyes are staring and dilated, and if touched give no response ; also the head when lifted is inert, and goes back to the same position when released. In some cases, however, the animal swings its head in a mechanical kind of way, and may grunt or moan. The rest of the body has the same paralysed appearance. Long strings of saliva may be seen coming from the mouth, due to inability of animal to swallow owing to paralysed state of the throat. The bowels and bladder are usually in the same state, but in slighter cases may not be affected. The temperature is normal, *i.e.*, about 102°. Breathing is slower, but in some cases there is a heavy stertorous respiration. Shortly put, the animal appears to be in a deep sleep.

Treatment.—Some cases recover in a half to one hour without any assistance, but very few. The best mode of treatment is the injection of air into the dder after it has been rendered pure. There are many apparatus for this purpose on the market which can be obtained at a reasonable price, *i.e.*, milk fever outfits.

To carry out the treatment properly, the following precautions must be taken, viz.—The udder and teats must be washed with warm water and soap, afterwards with some antiseptic solution such as lysol, washing soda,&c., and place a clean towel underneath. The teats should not touch the ground, where they might become soiled. Then, after boiling the teat syphon (found in outfit), insert into teat and pump until the quarter is inflated, and then tie the teat with piece of tape and repeat to other quarters. Air can be left in for two hours, and if animal is still down repeat process. Before pumping, however, milk out the udder to get rid of any milk.

The cow must be kept in an upright sitting position, so that she is resting on breastbone, and this can be maintained by placing bags of sand against her shoulders. In half an hour the animal is generally on her feet. If paunch is very much inflated, as may occur if the cow is allowed to lie on her side, puncturing may have to be resorted to.

In the case of bladder paralysis it is often necessary to introduce hand into the rectum, and by gently squeezing the bladder the contents are evacuated. After the animal is up for a few hours it is advisable to give 1lb. Epsom salts and 1oz. ginger in two pints warm water and treacle.

Preventive Measures.—Where animals are on green feed a week before calving take them off and put on to dry fodder, and in case of gross-conditioned animals a very spare diet is desirable. The administration of a purgative three or four days before calving is expected is advisable, such as Epsom salts, ginger, &c., in two pints water. A free access to salt and water is important. Where calving has occurred suddenly, administer a purgative.

CONGESTION OF UDDER.

This condition is often seen in heavy milkers just prior to calving and afterwards, the udder being enlarged, hot, and tender, and there may be some slight swelling for a little way along the belly. This condition is a natural phenomenon, and usually disappears in two or three days after secretion of milk has been fully established. Its disappearance can be hastened by massaging the udder with the hands, applying at the same time a little camphorated ointment two or three times a day. Sometimes the milk is left in udder for a whole day, as seen when animals are being exhibited at shows with the idea of making a great show of udder for sale purposes. The result is that the udder is inflamed, the bag pits on pressure, and the milk is often streaked with blood, and is partially clotted and drawn from the teat with difficulty.

This condition should be treated with hot fomentations, massage, and rubbing in of ointment as advised for congestion.

PEACH LEAF CURL FUNGUS.

(*Exoascus deformans*) Fuckl.

FURTHER TESTS WITH COPPER COMPOUNDS.

By GEO. QUINN, Horticultural Instructor.

In this *Journal* for August, 1911, a detailed account of the results of a series of spraying tests made with copper compounds against this fungus at the Government Experiment Orchard, Blackwood, during the season 1910, was printed.

In the following spring (1911) it was proposed to repeat the trials—and in fact the same sprayings were actually applied—but the season opened so unexpectedly early that the leaf buds had shot before the applications were made, with the result which was anticipated—the fungus had secured itself too deeply to be controlled by any of the reagents used, and the leaves in all sections were badly diseased, though those upon the trees treated with pure solution of copper sulphate were less so.

In the season 1912 the trials were again proceeded with, and a fifth compound added in the shape of a Bordeaux mixture based on the formula advanced by Mr. Spencer Pickering, of the Woburn Experiment Orchards in England, in which the milk of lime was replaced by clear limewater. A Bordeaux powder was also substituted for the Bordeaux paste.

The spraying compounds used were—

(1) Bordeaux mixture.
(2) Burgundy or copper soda mixture.
(3) Woburn Bordeaux mixture.
(4) Copper sulphate solution.
(5) Bordeaux powder (Bickford's).

The trees treated consist, with one or two exceptions, of the alternate rows of a block of Elberta peaches, planted in 1908 on an even and gentle slope, for use in a permanent manure trial. These are the barrier or unmanured rows between those being dressed with various fertilisers year by year. They are all well-grown specimens, about 8ft. high by 6ft. to 8ft. through the spread of branches.

The three rows treated with copper sulphate solution were sprayed once only, viz., on August 20th. Of those rows to which the other reagents were applied, viz., six, seven, eight, and ten, each received one spraying only. The rows dressed with ordinary Bordeaux mixture being sprayed on August 6th, whilst those receiving the Burgundy mixture, Bordeaux powder, and Woburn Bordeaux were treated on August 12th—six days later. The other rows, which received two sprayings, were treated on August 12th and 26th, excepting those on which ordinary Bordeaux was used, their first dressing being applied on August 6th.

The lesson of this season's trials—from the figures tabulated below—would appear to be the inadequacy of one spraying, whether given on August 6th as with ordinary Bordeaux, on 12th as with Burgundy, Woburn, or Bordeaux powder, or on 20th, when copper sulphate was used.

The average number of curled leaves per tree on those sprayed once with ordinary Bordeaux mixture was 75·66, against an average of three when sprayed twice. On the Burgundy-treated trees they averaged 11·33, against ·66 when treated a second time. The single dressing of Woburn Bordeaux yielded an average of 303·66 per tree, against 3·33 when twice sprayed. On those receiving Bordeaux powder once 4·66 diseased leaves were gathered per tree; those treated a second time showed an average of six diseased leaves per tree—a result which, it must be admitted, is somewhat perplexing.

At the times of the first sprayings the buds outwardly appeared to be almost quite dormant, but on August 20th there was evidence of movement in them, and by the 26th they (the flower buds) were clearly beginning to unfold.

Three " once with " " "	911	—
Nine " once with Copper Sulphate Solution	1,297	17
Three trees unsprayed (soil dressed with iron sulphate)	5,907	325

It would appear from the above comparison that the work of 1912 was less effective in suppressing the curl leaf fungus than the sprayings of 1910. As far as could be ascertained from observations made amongst peach plantations generally in the State, both seasons were productive of much curl leaf disease; but, assuming that in this respect the honors were fairly even, another factor of importance must be mentioned. This is, the trees, with few exceptions were those operated upon in 1910, when they were only three seasons old and bearing approximately only one-half the foliage they did in 1912. This increase in size would enlarge the mechanical difficulty of dressing all parts of the trees so thoroughly as would be possible in the case when they were of lesser statue. On the other hand, in so far as the remedies were concerned, effectiveness should not be lessened if the dressing be equally complete. The weather conditions usually accepted as favorable to the development of this fungus are a showery spring intermixed with sudden fluctuations of temperature. In the table below the rainfall occurring at Blackwood during the progress of the test in 1910 is given in weekly periods, but as these do not run on all fours with the weekly periods compiled for me for 1912 they cannot be closely compared.

In 1912, however, the tests began on August 6th, and were completed with the last collection of diseased leaves on December 11th, equalling a period of 19 weeks. In 1910 the trials began on August 15th and ended on November 22nd, with the gathering of all diseased leaves, or 14 weeks. A glance at the totals show that if the period covered by the date of the 1910 trial be taken in the 1912 rainfall records, the precipitation is 10·83in. in 1912 and 8·78in. in 1910.

Table showing the Average Weekly Rainfall and Average Temperatures, Minimum and Maximum, in the Soil at a depth of 2ft. 3in., and in the Shade, during the period the Peach Leaf Curl Spraying Tests were in progress in 1912.

In consulting these tables very considerable fluctuations will be noted in the temperatures, more particularly in the soil readings. As far as the writer is aware this is a phase of the subject of the study of the prevalence of curl leaf fungus as yet uninvestigated, and the records herein quoted may prove more enlightening as time goes on. Summing up the results of the two seasons' trials, and this in the light of the varying climatic conditions which prevailed, there is strong evidence that the Burgundy or copper soda compound is a splendid fungicide, in so far as its powers to repress the curl leaf of the peach is concerned.

When applied twice the ordinary Bordeaux mixture made with milk of lime is very efficient. The same possibly may be claimed for the Woburn Bordeaux; but only one season's trial is not sufficiently convincing. The Bordeaux powder bears out the promise of the paste, but further tests are desirable, as the results of one and two sprayings are somewhat contradictory.

The disappointing factor in the 1912 trial is the failure of the copper sulphate solution, which promised so well in 1910, and stood out conspicuously in the unrecorded sprayings of 1911.

The enormous increase in the number of diseased leaves on the trees which have never been sprayed shows very clearly that four years' dressings of the soil above the roots with ferrous sulphate has afforded no protection against the ravages of this leaf destroyer.

It may be mentioned that these unsprayed Elberta trees are a year younger than those in the rest of the plot, and markedly show the stunting effect of the repeated attacks of this disease. In conclusion, I desire to place on record my indebtedness to the orchardist at the Blackwood Experiment Orchard (Mr. Savage) and his assistants for the care taken in carrying out these trials.

FORESTRY IN AUSTRALIA.

By H. Hugh Corbin, B.Sc. (Lond.), B.Sc. (Edin.), Instructor in Forestry, Department of Woods and Forests, South Australia.

[Under the above heading comprehensive and useful information relating to forestry, compiled by Mr. H. Hugh Corbin, B.Sc., has been issued in pamphlet form by the Woods and Forests Department. The publication bears evidence of considerable research by the author and contains a mass of statistics which should prove exceedingly valuable for the purpose of record and comparison. Mr. Corbin states that the object of the pamphlet is to prove the value of our forests, and below will be found extracts which are most likely to concern the ordinary reader.]

BRIEF SURVEY OF THE AIMS OF ECONOMIC FORESTRY.

Economic forestry, aiming at the conservation of forestal wealth by safeguarding forests against inconsiderate destruction, and by the suitable reforestation of denuded areas, is essential to the preservation of industries dependant upon an adequate supply of timber, and to the perpetuation of a necessary form of national wealth. Though in Australia large areas of virgin forests still remain, the inroads made by timber-getters, by agriculturists, and by pastoralists—who have destroyed large areas by "ringbarking"—are considerable; and it is not unlikely that climatological changes are caused thereby. For it would appear that variations in climate, and alternating periods of drought and flood, desiccation and erosion of soil, with loss or diminution of fertility, have resulted from forest denudation in countries bordering the Mediterranean. In many of the States of America diminished rainfall is said to have followed the destruction of large forest areas. On the other hand beneficial consequences appear also to have followed on the planting of trees on denuded lands, or along encroaching coasts, and it is obvious that a forest covering tends to beneficially regulate the effects of rainfall.—(*Taken from the Commonwealth Year Book.*)

The above, which puts the case very briefly and well, reveals the state of affairs in Australia.

Timber of the World.—In the rest of the world the land surface has a certain large proportion of forest which has from time immemorial been developing giant forest trees—many of these individuals have taken centuries to grow. Amongst them are also many smaller and younger trees and seedlings. This is the condition prevailing in the virgin or primeval forests.

Reduction of Forests by agency of Man and Fire.—Owing to the vast increase of the population of the world and the spreading of the white races over the later discovered continents, and their extraordinary capacity for using wood, these primeval forests have been enormously reduced in extent, and the old, bulky timber has been wastefully cut down and shipped to the large industrial centres and there put to innumerable uses.

Fire has been the next most destructive agent, and in America, Russia, Siberia, and India, and many other places, thousands of square miles of standing forest timber have been destroyed.

Scarcity of Timber being Felt.—The result at the present time is that large and sound timber on the market has become almost a thing of the past. That which is available can only be obtained at very big prices, owing to its being scarcer and the fact that the lumberman has to go further afield. The price of timber is likely to steadily rise for many years, especially for good quality lumber, and there can be little doubt that the present steps to conserve and afforest are inadequate. The vast inroads of civilisation into the " wood capital " of the forests have made it necessary for the lumberman to utilize inferior and immature timber in order to meet the demand for certain classes of wood. The situation is becoming such that timber-exporting countries are raising their export duties on forest produce ; the destruction of their forests is endangering their national prosperity, and they are realising this. They are vigorously conserving and repairing their forests, also in many cases afforesting new areas in the hope of being able to produce enough timber for their own consumption in the future, and at the same time prevent erosion and conserve moisture, maintain moderate climatic conditions, and generally foster the resources of the land. The utility of forest areas on a reasonable scale is proved beyond doubt. For information on this subject it is only necessary to read modern literature.

Wood Capital.—From the point of view of timber only, the difficulty is that trees grow but slowly and cannot be profitably cut until they have reached a certain stage of maturity.

The felling of these trees which are already mature continues at such a rate that in a comparatively few years mere saplings will be the only timber available. In other words the wood capital of the world is being consumed rapidly.

As an example of the above the United States Forestry Department publish statements to the effect that some of the Californian Redwoods Sequois are of great antiquity. One tree is known (by counting the annual rings) to have attained at least 4,000 years ; these giants are nearly all gone.

Australian Growth.—Here in Australia, however, we have a distinct advantage over many other climates in that wood grows much more rapidly, and, therefore, the production of volume of wood is not such a waiting game ; but who can say how old many of our larger forest trees are, and can we wait until our younger trees attain maturity ?

Substitutes for Wood.—It has been urged that metals will take the place of timber, but in the United Kingdom, where metal, &c., is enormously substituted for wood, the importations of wood are very heavy, *e.g.*—Value of imported timber—1907, £27,093,054 : 1908, £24,306,169 ; 1909 £23,591,579. 1910, £26,207,329 ; 1911, £25, 62 171.

Probably only a trace of this is exported again, except after being converted into articles of use.

Wood More and More Indispensable.—It is beyond all doubt that wood is indispensable, and as the population of the world increases more and more will be required ; hence there seems to be little risk of the over production of wood.

Exhaustion of several Important Varieties of Timber and Degeneration of Quality.—Already several species of timber are practically exhausted—European oak, ash, beech, walnut—small and inferior Oregon pine are shipped now instead of the superior quality and more or less knot-free pines and Baltic deals, and knotty, small trees only are available. New Zealand kauri will only last about 15 years at its present rate of consumption, jarrah and Californian redwood are heavily exported, and will become scarcer and more costly, and eventually disappear as an article of commerce.

The general deterioration of forests and hence the increasing difficulty of getting good timber at reasonable prices is common knowledge to those interested in timber. It is difficult to predict the state of affairs which is likely to obtain, say, in 20 years' time ; but there seems every indication that good timber land will get more and more valuable and that most countries will be forced to invent wise policies with regard to timber production, and will undoubtedly be conserving and planting on areas which are capable of yielding high returns of timber, on some of their best land for production of the timber of the future. With modern scientific methods forests offer a very sound investment.

What is required now in Australia is public sympathy and support, and practical scientific forestry. It would be a pity to leave the consideration of these matters until much expenditure is necessary to put things right. At the present time much of the country called " forest " has very few trees to the acre. Proper forests can hardly be said, speaking quite generally, to contain less than 100 trees to the acre, and these should be large timber trees—60ft. to 100ft. high or more. When trees are less dense the country merges into park country, and, as they get fewer, into open timbered country.

The forests of the future will consist of trees which will afforest more or less densely, and they will not be very old when claimed by the axeman.

Australia Grows Some of the Finest Hardwoods in the World.—In Australia there are many extensive valuable forests which must be looked to to ultimately provide timber in the place of imports. Australia has the advantage of a variety of climates, and should be able to provide timbers which, though not identical with those imported, should be quite as satisfactory.

South Australia, although not so densely wooded as some of the other States, is yet quite capable of producing timbers in sufficient quantities and of such nature as would replace the greater part of the enormous importations.

There are many localities in this State where the soil and climatic conditions are such that a great variety of species is possible. This is rendered obvious by the fact of the presence of fine specimens of trees here and there about the country. The argument that some of the choicer species do not grow as quickly as some of the other species is poor, because quick-grown timber is necessarily lighter and inferior. Moreover, a variety of species is essential, since it is certain that one species cannot serve all purposes. The great point is for Australia, and especially South Australia, to make the most of these choicer localities where valuable timbers can be produced.

Responsibility of Forest Officers.—It is essential also to have men in charge of timber-producing areas who know forestry from all points of view, because incompetence on the part of the officer in charge may mean that the timber produced is inferior or useless owing to its not having received the correct treatment while growing. In fact, this responsibility is usually made to rest upon several officials.

Carelessness, ignorance, lack of watchfulness, or incompetence of any kind is bound to revert on the revenue-yielding capacity of the forest, *e.g.*, failure to observe an outbreak of fire in a dry time of the year means probably the destruction of thousands of pounds worth of valuable timber. The same remarks apply, though to a less extent, to outbreaks of insect or fungoid attacks. Fire is usually guarded against by organising firebreaks and a system of forest telephones to enable the outbreak to be checked in its infancy.

These precautions, however, vary with the value of the timber. A valuable forest should be well staffed, and the rest follows. The responsibility of a forester is always greater than that of the manager of agricultural land, because the forest represents the accumulated interest of many years, *e.g.*, an acre of forest may contain easily 500 trees which have been growing 40 years, and are worth 10s. each on an average at the lowest estimate, or total value equal £250 (some areas of timber are worth much larger sums); whereas an agricultural crop represents only one year's interest on capital, and may be only worth per acre, say, £20-£30 at the most when fully mature. Therefore foresters must be thoroughly reliable and skilled in their work.

Foresters should also be charged with the responsibility of daily meteorological observations, which are of such importance not only to themselves but generally outside the forest ranges.

Wheat and Forest Land.—It has been said that wheat produces a higher revenue than timber. No doubt this is true of certain soils and certain localities, but the reverse is also true about other soils and localities. This matter is merely a question of the judicial selection of a site suitable for the crop.

A treeless country must of necessity import timber for its own use, often at high cost; therefore, for this and other reasons, a certain amount of timber area is essential in each and every country if it is desired to obtain the fullest benefit of the soil at the lowest cost. Forests are being fostered even in Egypt.

One thing that seems very advisable is to concentrate the available resources on well-chosen and extensive areas where timber will best develop, and thus reduce the cost of administration and increase its efficiency. Many small reserves are bound to be expensive.

Forestry and Labor.—Another matter of great importance is labor. Labor is a *sine qua non* even in forestry, and there is no doubt that with regard to wattle-stripping it has lately been uncertain in South Australia. However, the question of labor applies to every industry. Prosperity and development cannot exist in the absence of satisfactory labor. It is clear, also, that it is as much in the interest of the laborer to help to develop the essentials of life, *e.g.*, wood, tanning bark, wherewith the leather for his boots may be made, &c., as it is in the interest of any other unit of the community. One of the great advantages forestry offers to the laborer is that it provides a very congenial, interesting, profitable, and healthy way of earning a living, and supplies with raw material many subsidiary industries in which his fellows may seek employment. Forestry may be managed so as to provide continuous and steady employment throughout the whole year.

Forestry assists in the development of the land and tends to relieve the congestion of population in the towns, and is one of the most important matters of the present day, especially in a new country such as Australia.

Forestry and Shelter.—This account is intended to deal more with the financial side of the subject and less with the other aspects, such as the advantage of shelter belts in protecting young and delicate crops from the tempestuous and scorching winds, and the fact that timbered country conserves to some great extent the rainfall and prevents erosion of the land surface.

However, it is worth noticing that high authorities in the matter of crops are of opinion that many of the sandy patches and stock roads of the country could, with advantage, be planted with trees for the purpose of shelter belts and timber. It would be a means of utilising these areas, which are at present considerable in extent and unproductive. It is well known that trees in shelter belts protect the land from fierce, hot winds in summer and cold blasts in winter. This matter wants to be systematically taken in hand.

In a country where there are many hot, dry months, and the rainfall is very unevenly distributed throughout the year, the need of conservation of moisture is great. Shelter belts and timbered areas should therefore be fostered with more care than in more humid climates.

It is impossible to estimate the benefits derived directly and indirectly from timbered country, but it is now generally recognised that forestry is essential to the well-being of each and every country.

United States	1,000,000	33·67	860,000	24·08
Canada	1,248,800	33·34	836,000	22·33
Cape Good Hope.............	537	0·19	537	0·19
British India	107,125	9·85	128,890	11·74
Japan	27,298	18·49	28,450	19·00
Average	..	18·8	..	19·37

In this table the following points are worth notice: —

1. These figures are necessarily only approximate, but nevertheless valuable.

2. The tendency of all the progressive nations is to increase their area of forests.

3. The United Kingdom, Algeria, Roumania, and the Cape of Good Hope have all very low percentages of forest land. Australia has also a very low percentage, but it has also large deserts. An endeavor should, however, be made to possess an adequate permanent area of good timber country. It is unnecessary to state an exact per centage, but from the above table the average of all countries cited is about 20 per cent. Therefore, in Australia there is probably room to develop out better forest areas and make them bear a reasonable proportion in point of dimensions to the habitable area of Australia.

4. Where there have been extensive primeval forests the inroads of civilization have been very heavy (*e.g.*, Canada alone having between 1906 and 1910 reduced its forest area by 412,800 square miles ; America has also lost 140,000 square miles of forest in the same time). This reduction is due to settlers and agents clearing forest lands to make room for homes and farms. There is no doubt great necessity for clearing and the conversion of some of the timber into other necessities, especially in a new country, where probably at first the only source of wealth is timber. Cf. Tasmania, pp. 5 and 6 How long will its timber last ?

Theodore Roosevelt, however, said, in 1905, in an address to the American Forestry Congress, " You all know the individual whose idea of developing the country is to cut every stick of timber off it and then leave a barren desert for the homemaker. That man is a curse, not a blessing, to the country." But it is also a fact that millions of acres of valuable timber in Canada and the States have been devastated by careless, selfish individuals ; fires have also been started in country heavily timbered and which is quite unsuitable for agriculture.

SUMMARY.

The total value of timber, as declared at the Customs, imported into the Commonwealth during the period 1901-1910 = £14·55 millions.

The total value of timber, as declared at the Customs, exported from Australia during the period 1901-1910 = £6·849 millions.

Therefore considerably over £21·39 millions worth of timber is cut or used in the Commonwealth, excluding that which does not pass the Customs and is locally sawn.

	Millions.
Value of timber imported into the Commonwealth—1901 =	£2·085
Value of timber imported into the Commonwealth—1910 =	£3·547
Value of timber exported from Commonwealth—1901.... =	£0·666
Value of timber exported from Commonwealth—1910.... =	£1·020

If the timber locally sawn be considered in addition to the above, it is evident that the total value of wood utilized in the Commonwealth is very high.

The value and quantity of timber imported into the Commonwealth are increasing yearly.

The value and quantity of timber exported from the Commonwealth yearly are not increasing in a similar way.

South Australia alone has imported during period 1905-11 from over the sea £1·843 millions worth of timber, and during 1905-09 from other States in the Commonwealth, £542,248 worth.

The average annual importation of timber into South Australia is well over £370,000, and this is increasing steadily.

The world's timber-yielding forests are decreasing in number and extent, while the population of the world is increasing rapidly.

The world's rate of consumption of good, sound timber is probably many times its rate of production.

Wood is indispensable, and its consumption has increased in spite of the substitution of metals and other material.

Progressive countries are conserving and afforesting on scientific business lines, and not allowing a few mercenary individuals to dissipate by wasteful methods the national wealth represented in timber, the destruction of which causes deterioration of the land and crops.

Australia has over 150,000 square miles of "forest," of which in 1910 27 million acres were specially reserved for timber.

Selected portions of these should be put in order, and to do this skilled foresters are necessary.

Taking the Commonwealth figures it is seen that the revenue of the State forests is every year nearly double the expenditure. Figures for 1910-11—

Expenditure	£110,923
Revenue	£203,256

Much might be done to develop the subsidiary industries of the forests.

Several parts of Australia have different climates, and therefore it should be possible to produce sufficient varieties of timbers for all purposes, which should in time obviate the necessity of extensive importation.

RECOMMENDATIONS.

The main objects of forestry to be achieved in Australia are—

(1) To carefully develop in commercial quantities the indigenous timbers which are suitable for commercial purposes.

(2) To carefully establish and develop exotic timber trees which will grow in the various States, also in the choicer localities develop the choicer species in order to produce as much variety of timber as possible.

The above two lines of work are most important in view of the costly importations.

(3) To develop the utilisation of these timbers and the best methods of seasoning, and treating by impregnation the more pervious and inferior species to render them more durable.

(4) To draw attention to the possible by-products of the forests and the possible subsidiary industries.

(5) To improve the climatic conditions locally and conserve the rainfall as much as possible.

(6) To introduce a proper and comprehensive system of education in the matter of trees in order to stimulate public interest in the work of tree culture.

(To be continued.)

CONTROL OF ORCHARD PESTS.

At the last meeting of the Blackwood Branch of the Agricultural Bureau, the Hon. Secretary, Mr. C. G. Savage, contributed an interesting and instructive paper on the control of orchard pests.

Mr. Savage said—In dealing with this subject it is necessary to understand something of the disease which we wish to control. We can split our subject into two divisions, viz., (I.) *Insect Pests,* which we my divide into two subdivisions—(*a*) *Mandibulate,* or chewing insects ; and (*b*) *Haustellate,* or sucking insects. (II.) *Fungus Diseases.* In this division we have—(*a*) *Epiphytic*—fungi which grow on the surface of the leaves and young shoots and send their root-like portions into the plant cells ; and (*b*) *Endophytic*—fungi which live in the internal cells of the plant.

With these few points before us we can understand why all sprayings for insect pests, for example, are not the same. It is easy to realise that if we cover our tree with arsenate of lead in hopes of killing a sucking insect, we are wasting time and material, as the insect thrusts its sucking tube through the epidermis of the plant and feeds on in spite of the poison.

I propose to deal with each section separately.

I.—INSECT PESTS.

Chewing Insects.

The principle insects in this division with which we have to contend are codlin moth, curculio beetle, and cutworms.

The treatment for codlin moth is a familiar one to all. It consists of spraying the trees with some arsenical compound, preferably arsenate of lead. Having procured a reliable brand of the arsenate we must be very particular when and how we apply it, bearing in mind that the first spraying is the most important. This should be applied just after the petals have fallen and before the calyx cups of the young fruits have closed. Owing to the rapid growth of the fruit and the continuous hatching out of the caterpillars at this stage it is desirable to repeat the spraying in about seven to 10 days. The strength of the spray washes will differ slightly, according to the brand of arsenate used, but 3lbs. to 50galls. of water is about the average. It will be well with the first spraying to see that some of the poison lodges in the calyx cups, as many of the caterpillars enter at that end. There are two and often three broods of caterpillars during our season, and it is necessary to apply a third spraying, and often a fourth at three or four weeks intervals.

We can greatly assist in overcoming this pest by scraping off all dead and cracked bark from the trees, cleaning knot holes, and keeping the orchard free from rubbish, as these are the natural hiding places for the full-grown caterpillars. Traps may be set by tying bagging around the stems of the tree, under which they will seek shelter. These traps should be examined every week and the caterpillars killed. If these bands are not systematically examined they should be left off altogether, otherwise we are merely harboring the enemy.

The Curculio Beetle is not a common pest in this district, so far as I am aware, but I have seen the effects of it upon a few trees. As it does much damage in other parts of the State, a word or two in relation to its control will not be out of place. Spraying the trees with a solution of 1lb. of arsenate of lead to 8galls. of water will help in diminishing the pest. Do not spray until the mixture runs off, but merely coat the leaves with a mist-like spray. It is well to bear this point in mind in spraying for other chewing insects, the reason being that when the mixture runs off the plant it carries most of the poison with it and we get left only a small amount of arsenate coating the apex of the leaves. The mist-like spray covers the whole surface of the leaves and evaporates rapidly, leaving the poison distributed evenly over the foliage. Dusting the trees with Paris green and flour gives good results. These materials should be mixed in the proportion of one of green to 50 of flour, and applied while the foliage is damp.

For Cutworms, spray the trees with a strong solution of arsenate of lead, or lay poison baits. The bait may be made by mixing the following:—8ozs. Paris green, 4lbs. molasses or sugar, 30lbs. bran, with sufficient water to make a paste. Place small portions of the mixture around the stems of the trees, but not against them.

Sucking Insects.

In this section there are the scales, aphides, and the pest commonly called red spider (*Bryobia pratensis*) with which we have to contend.

Red Spider.—This pest (which is not a tree insect) has been working havoc among the gardens on the plains during the season that has just ended, and may be treated at this season of the year by spraying with red oil compounds and lime-sulphur washes. I will deal with the making of lime-sulphur sprays later, but would like to call attention here to one of the latest American bulletins relating to tests on the control of red spider. In the experiments under notice the lime-sulphur wash was used, and to this was added flour paste, the paste being made by pouring and stirring 4galls. of boiling water on to 4lbs. flour. This was then added to 100galls. of spray wash. The paste was used as a spreader of the spray, and could no doubt be used advantageously with other contact insecticides. This spray will not kill the eggs of the red spider, and a second application of the wash should be applied as the young emerge.

Scales.—The most effective way of dealing with these insects is by fumigation with hydrocyanic acid gas under air-tight covers. Spraying with various washes, of which resin wash has proved one of the best, greatly minimises the pest. Resin wash is made as follows:—Resin, 10lbs.; washing soda, 10lbs.; fish oil, 1½ pints (if procurable, if not use 5lbs. of soap); water, 50galls. Put the soda in sufficient water to allow it to boil freely; when dissolved gradually add the soap or oil, then slowly stir in the powdered resin, and boil rapidly for an hour, adding a little water from time to time to prevent the mixture boiling over; finally add sufficient water to make 50galls. We could also use lime-sulphur wash against this pest.

Aphides.—In this district we are mainly troubled with the black aphis of the peach, and we have remedies in resin and tobacco washes. This pest rapidly reproduces its kind; hence the necessity for several sprayings at intervals of seven to 10 days. Resin wash prepared as described and diluted to half the strength recommended for scales will prove effective. Tobacco wash may be prepared as follows:—Tobacco, 4ozs. to 8ozs.: pour over this ¾gall. of hot water and allow it to steep overnight, or if in greater haste simmer the tobacco over a slow fire for a couple of hours. Dissolve 2ozs. of soap in 1qt of water and strain the tobacco solution into this; a little resin wash may be added with advantage, or the addition of flour paste should prove effective. We should bear in mind that these insects are destroyed by suffocation, and this is done by bringing the spray washes in contact with their bodies and thus stopping up their breathing pores. The mixtures will give better results when sprayed on with force, and especially is this the case with the American woolly blight, which insects are covered with waxy filaments.

II.—FUNGUS DISEASES.

Epiphytic Section (External Fungi).

Mildews are the only diseases under this head that we need mention, and they are controlled by dusting flowers of sulphur over our plants. The sulphur is best applied in the early morning when the dew is on the plants, as it will not blow away so readily as it will when applied while the trees are dry.

Endophytic Section (Internal Fungi).

In this section we have the most troublesome of the fungus diseases, viz., peach curl leaf, shothole and scab of apricot, black spot or scab of the apple and pear, and gumming blight of peach, almond, apricot, &c. The remedies for all these diseases are found in the bluestone washes and lime-sulphur sprays.

Peach Curl Leaf.—The spraying must be done before the buds burst, just as they are swelling, and if the variety is very subject to the disease, or if the trees were badly affected during the previous season, spray when the buds are dormant and then follow up with a second spraying as they begin to swell. I would like to point out that it is a waste of time, so far as curl leaf is concerned, to spray after the leaves have expanded. The spores of the fungus lie lodged under the scales of the buds during the winter and when the sap begins to move in the tree and the buds to swell, the spores germinate and enter the young growth. If our spray mixture is upon the tree the young fungus growth comes in contact with it and is destroyed; if the spray is absent the fungus enters the plant and plays havoc, although we may spray our trees afterwards. For two years we have carried out spraying tests for the prevention of this disease with the following results :—

Spray.	No. of Sprayings.	No. of Trees.	1910. No. of Curl Leaves.	1912. No. of Curl Leaves.
Bordeaux Mixture	2	6	14	18
“ “	1	3	10	227
Woburn Bordeaux Mixture	2	6	not used	20
“ “ “	1	3	—	911
Burgundy Mixture	2	6	—	4
“ “	1	3	—	34
Bickford's Bordeaux Paste	2	6	—	not used
“ “ “	1	3	158	—
“ “ Powder	2	6	not used	36
“ “ “	1	3	—	14
Copper Sulphate	1	9	17	1297
Sulphate of Iron	—	3	325	5907

The trees in the last test were not sprayed, but ¼lb. sulphate of iron was forked into the soil around each. The variety of peach in all the tests was Elberta.

For Shothole and Scab of the Apricot, spray when the flowers are opening and again when the fruits are half grown. For black spot or scale of apple and pear, spray when the blossoms are opening, and repeat the spraying after the flowers have formed. The copper solutions may be mixed with the arsenate of lead sprays, thus saving the double amount of work.

For Gumming Blight, spray with the copper solutions as soon as the leaves have fallen in the autumn and burn all prunings from the affected trees.

FORMULÆ FOR SPRAY WASHES.

Bordeaux Mixture.—Four pounds bluestone, 3lbs. of fresh lumpy lime, and 40galls. of water. Dissolve the bluestone in 20galls. of water by suspending it just under the surface. This point is important, because if the copper sulphate is placed in the bottom ot the vessel it will take days to dissolve, but if hung near the top of the liquid it will dissolve in a few hours. When ready to spray slack the lime by slowly adding a little water, and when the lumps have crumbled to powder make up to 20galls. Run the bluestone solution and limewater gradually together in a third vessel and stir the mixture.

Burgundy Mixture.—Four pounds bluestone, 7½lbs. washing soda, and 40galls. of water. Dissolve the bluestone as before in 20galls. of water, dissolve the soda in another 20galls., and mix the solution by running them slowly into a third vessel. It is well to remember that in dissolving copper salts metal vessels should not be used, but wooden ones, as the action of the copper on the metal will soon destroy the vessel.

Lime-Sulphur Spray.—This wash is coming greatly to the fore of late years, and although not a common spray here is being used largely in some of the other States. The winter sprays may be made as follows:—Lime slacked under water three weeks before using, 6lbs.; sulphur, 12lbs.; soft water, 100galls.

A bag at a time may be slacked as above; and provided that the lime is always covered by the water, it is ready for use at any time required. Take 12lbs. of sulphur, mix it into a paste with 2½galls. of boiling water, add to it the 6lbs. of the lime paste and an additional 2½galls. of hot water, mix and divide the solution equally into two 5-gall. cans; boil from one to one and a half hours, keeping well stirred, and from time to time adding a little cold water to prevent loss in boiling over. Then make the whole up to 100galls., and strain before using. There is no fear of the mixture clogging the nozzles, and if the lime has been slacked as directed, no scalding to the operator takes place; at the same time it is advisable to keep the hands oiled. Keep the mixture well agitated whilst spraying. It may be applied cold. Many formulæ are used, and this one has given very satisfactory results. Be careful to use an iron vessel, as it will destroy vessels made of copper. On account of the lime-sulphur spray being quite caustic, it will soon make one's hands sore; it is therefore important to see when spraying is carried out that all connections on the pump and hoses are tight. Leather gloves should be used and the hands kept well greased. The horses and harness, when using large outfits, should be protected by a light cover. When left standing overnight, re-treating is necessary owing to the formation of sulphur crystals. When the mixture is well made it becomes a dark-reddish yellow, and should take from 45 to 65 minutes to prepare. There should be very little sediment.

A self-boiled lime-sulphur wash—lime (fresh lumpy), 16lbs.; sulphur, 16lbs.; water, 100galls. This mixture is suitable for spraying peaches or cherries, but is not so desirable for spraying apples. To prepare, put the lime into a barrel, add sufficient water to nearly cover it and to start the slacking. As soon as the slacking has well begun, add the sulphur, which has been rubbed through a sieve to break the lumps. Stir continuously, adding water as it is needed to prevent thickening, drying, or burning. As soon as the slacking ceases add the required amount of cold water, or enough to prevent further action of the heat. The boiling should not continue long enough to cause the formation of much brownish-yellow liquid at the top of the slacking barrel. For summer sprayings the mixtures should be diluted to about half strength. Stock solutions of concentrated mixtures may be made, stored, and diluted as required.

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

OPERATIONS FOR AUGUST.

Green Food for Summer Use.

The following green fodders may now be planted :—

Lucerne, the most valuable and productive of all fodders, will grow in most parts of the State. Thoroughly prepare the land, grade for irrigation, and sow mixed with bonedust. Seed, 6lbs. to 10lbs. per acre, bonedust, 100lbs. The seed should be lightly drilled in, so as to fall in the drills and not be buried. Cover with bush harrows. By drilling 7in. to 10in. in the rows the young plants can be cultivated and the ground kept clean. Keep the fowls away from the plot for the first year, otherwise they may injure the plants. Keep weeds down, and after each cut stir the surface. Later on—after each cut—give alternate dressings of bone super. and potash. South Australian Hunter River seed is excellent.

Silver Beet.—On well-prepared and manured land the seed may be drilled in rows 24in. to 30in. apart. The plants are afterwards thinned out to 15in. apart. For small plots sow a small seed bed and then transplant. Enrich the site of each plant with a little bonedust well-worked into the soil. The improved varieties of silver beet give splendid yields, and the plants last throughout the season.

Kails.—Jersey tree, Thousand-headed, and the French kail (Chou Moellier) are all well-adapted for the small or the large grower. Plants are obtainable from seedsmen, and should be planted out 30in. apart and 3ft. in the rows.

Other Fodders.—In some localities barley, oats, and rye may be sown, and will, if the season be propitious, yield a fine supply of palatable green food. Lettuce (cabbage) and the endives may be planted out in rows 18in. apart and 12in. between the plants. Endives are valuable for the high contents of minerals and salts. A bed of onions and another of garlic are well worth growing. Both should be fed to the breeding stock and the chickens. If fed to layers of eggs for human consumption they will impart an unpleasant flavor to the eggs.

FEEDING.

Breeders.—Give but little mash in the mornings, and for the heavy breeds let it be half bran, and use plenty of cut green food mixed in the mash. The bran should be scalded and then the pollard and green food should be incorporated, so that the resulting mass is well-mixed, semi-dry, and flaky.

Green Food, cut or suspended in bundles, may be feed two or three times a day. Use as much as the birds will eat.

Grain.—Good, hard, clean wheat, free from smut, should be fed in the scratching litter. Occasional feeds of peas, a little maize, and good stout potato oats may be given ; but all must be well scattered in the litter so that the birds must work hard for their living.

Grit.—Charcoal (¼in. cubes), sharp quartz, and shell grit should be placed in a hopper suspended where the birds can reach it, but yet cannot scratch the contents out of the hopper.

Water.—Use vessels which can be easily cleaned. Keep these clean—scrub them, scald them, and keep them in the shade away from filth. Fill twice daily with clean, fresh water. See that they are large enough and that enough vessels are in use for the flock.

General.—Do not overfeed. A few senseless people starve their birds, but the majority incline towards too liberal treatment. Give breeders a small feed of mash in the morning—the layers can have just as much as they will clean up in ten minutes. House scraps are excellent, but in many houses the supply exceeds the proper demands of the few birds kept, and in consequence the common troubles result from over-feeding. All soft food (mashes, etc.) must be fed in clean pans, and must not on any account be thrown on the ground nor in the scratching litter. Grain should not be fed in pans, but must be well scattered in scratching litter.

FEEDING CHICKENS.

Give chickens plenty of fine grit (sharp sand, fine charcoal grit, shell grit) ; of this they will consume a surprising amount, and without it they do not thrive. Finely-cut green food should be fed to them hourly—barley, barley grass, oats, rye, lettuce, kails, beet, &c. All growing ends and succulent growths are what they need and what they like. Years of experience show that hard feeding for the first few weeks gives the best results. There are several excellent chicken foods on the markets, but it is economical for the breeder of hundreds of chickens to buy a good grit mill and prepare his own feeds.

For the first week, wheat cracked into pinheads and screened on a fly gauze screen is the most satisfactory. After a week one may add hulled oats, skinless barley, a little maize—all cracked into coarse pin-head size—and a sprinkling of canary seed and millet, will afford variety. The fine meal may be saved, and after a few weeks may be mixed with bran and pollard, or, better still, with whole wheat meal, or a meal made of wheat, oats, barley, and a little pea meal. Scald enough bran to dry off a proper supply of the meal and feed it to the chickens in a semi-dry, flaky mass. As the chickens grow stronger the mash may be made firmer and fed on pedestals. The firmer mash or dough is better for fattening, and makes the chickens plump-up and grow quickly. Cracked grain mixture is fed at intervals in cocky chaff or other fine scratching material.

Earth worms are much relished by chickens. Bullock's liver, well-boiled, may be broken up and incorporated in the mash daily—only use a small quantity. Meat meal soup is also excellent and promotes growth.

DUCKLINGS.

Ducklings do well on scalded bran dried off with pollard and plenty of cut green food. Scald the bran with boiling milk or meat meal soup and allow it to swell; then mix in the pollard and green stuff. Give as much cut green food as they will eat. Provide grit in pans, as ducklings will eat large quantities. Grit may be mixed with the mash. Give no grain.

Ducklings must have *drinking water* available *day and night*. Keep it in vessels deep enough to permit the ducklings to totally immerse their heads. If ducks become thirsty at night and cannot obtain drink they will collapse in the morning after a drink.

TURKEYS.

The breeding season for turkeys is at hand, and the birds should be in good condition. Feed liberally on grain. Let the birds have as much liberty as possible. Give green food at all times. The chicks have small crops, and must be fed little and often. Feed as advised for chickens. Add to the mash finely cut onion tops or onion bulbs and garlic corms cut fine.

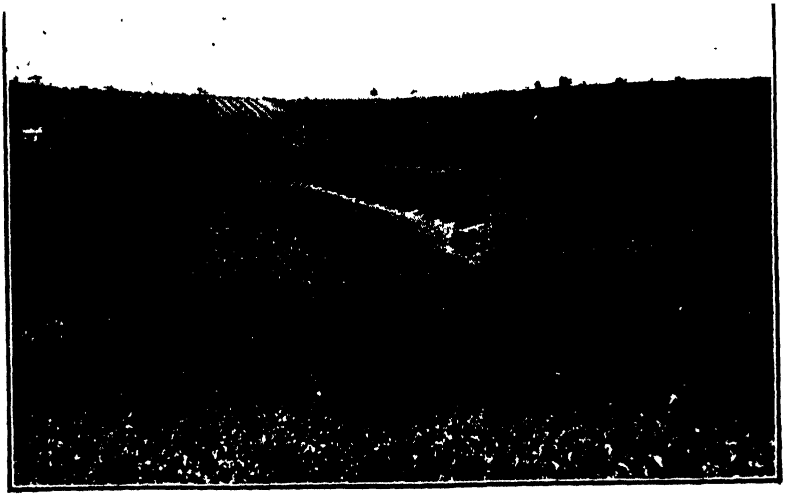
THINGS TO DO.

Keep your poultry yards and houses clean and well-drained. Fill up all hollows. See that the houses are dry and sweet. Protect the brids from draughts. Examine your stock and see that they are free from vermin. Use insect powders and provide dust baths. Study the article on "Poultry Parasites" in this issue. Examine your premises for poultry ticks, and eradicate them. If your neighbors breed ticks and other vermin, and have diseased poultry on their premises, promptly advise this department. Single test your pullets before breeding from them. If you do not understand the system send for a Bulletin on the subject. Do not breed from hens which lay small eggs. Do not use eggs for setting which are very small, very large, rough-shelled, or misshapen. Rough shells are due to inflammation of the oviduct. Misshapen eggs are caused by internal fat and sometimes by malformations. Wash the eggshells before marketing the eggs. If sending a distance use proper egg cases fitted with fillers. Collect the eggs daily and store in a cool, well-ventilated cellar. If you have no cellar, excavate one, using the excavated soil to cover the roof.

Market only infertile eggs. Test all eggs before forwarding them. Reject any egg which is not absolutely fresh. You ought to get more money for fresh infertile eggs. Sell direct to the retailer or the consumer.

Confine your operations to one breed. If you want eggs only, the White Leghorn of approved laying strain is what you require. If you want a fair supply of eggs and good table birds, select White Wyandottes, Rocks, White Orpingtons, R.I. Reds, Langshans.

Do not overcrowd your fowls nor neglect them, nor expect them to lay if deprived of proper food. Do not throw egg shells among the birds—this practice will encourage egg-eating. Do not expect to breed high-class layers from cheap rubbish. Do not plead ignorance when you can easily apply for advice. Do not claim the honor due to another breeder. Do not fail to read these notes each month. Do not be backward in writing for information ; it does not matter whether you have one hen or a thousand. Do not house your birds in those wretched eyesores termed poultry houses, and so common in the suburbs. Do not hustle your fowls ; treat them kindly and keep them tame and quiet. Do not fail to visit Parafield Poultry Station, and note the systems of housing, hatching, and brooding in vogue. Visiting days first Wednesday and fourth Saturday in each month.



Vineyards, Near Adelaide.

* * *

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

HEALTH.

The birds are all looking exceptionally well, and there have been no cases of sickness.

DEATHS.

Five deaths occurred during the month, and all were due to cannibalism. Three cases occurred in one pen and two other cases in other pens, in one of which a case occurred last month. From observation it appears that certain strains are inclined to this trouble.

BROODINESS.

Two cases of broodiness occurred—one in section 1, White Leghorn, and the other in section 2, White Wyandotte.

WEATHER.

The month has been generally dry and windy; fine and cold in the mornings. Rain was recorded on six days, and the precipitation was about 1·1in. A rain gauge is being erected, and rain and temperature observations will be taken daily in future.

TINTED EGGS.

Tinted eggs among the White Leghorn pens are very numerous this season. Last year at Roseworthy there were very few. This season, however, a large number have been noted and are recorded. The brown tint in most cases is marked. Leghorns should lay eggs with pure white shells. The tinted shell is an undesirable character and should be eliminated. This is a point which breeders must make special note of.

EGG PRODUCTION.

The egg yield for the month is highly satisfactory. Various would-be authorities criticised the methods adopted, and offered opinions which they are not qualified to give. The predictions have failed. Scores did not fall off either in June or in July—both months showed a steady increase. Facts prove the wisdom and the value of the methods adopted. The birds are in the best health and the egg yield is gratifying. One pen, Mr. D. Kenway's Black Orpingtons, made a fine weekly score of 41. The "possible," 42, has never been recorded in a South Australian laying competition. The totals of eggs laid and the averages per pen of six pullets are as follows:—

Section 1....	104 pens ..	10,962 eggs ..	105·4 average per pen
" 2....	23 " ..	2,471 " ..	107·4 " "
" 3....	28 " ..	3,060 " ..	109·3 " "
Total	155 pens	16,493 eggs	106·4 average per pen

For 155 pens to average 106·3 eggs=17·7 per hen for the month is an excellent performance. The feeding is as usual. An excellent supply of green barley, oats, &c., enables all the stock to have an abundance of green food.

WEIGHT OF EGGS.

Regulation 12 states—"Any pens the eggs from which do not attain an average weight of 24ozs. per dozen by July 31st, 1913, will be ineligible to participate in the prize money and will be returned to the owners." On July 31st the eggs of each pen were set aside for the official weighing. The results, which are shown in the following table, are very satisfactory. There are only four pens which failed to produce eggs weighing 24ozs. to the dozen. This represents roughly 2·6 per cent. Thirty-nine pens just reached the required standard, and to the owners of these I would offer timely warning that they are in a dangerous position. Thirteen pens recorded quarter of an ounce above the standard, and the breeders of these are reminded that the margin of safety is too small. The public is becoming informed upon many points relating to poultry-breeding, and demand is for stock which will produce a standard size, or even larger eggs.

The following table shows the number of pens the eggs from which attained the weights given :—

Weight.	Number of Pens.	Weight.	Number of Pens.
27¾ozs.	1	25ozs.	13
27½ozs.	1	24¾ozs.	16
27ozs.	1	24½ozs.	15
26¾ozs.	2	24¼ozs.	13
26½ozs.	3	24ozs.	39
26¼ozs.	2	23ozs.	1
26ozs.	11	23¾ozs.	1
25¾ozs.	9	22½ozs.	1
25½ozs.	16	22¼ozs.	1
23¼ozs.	9	Total	155

DISQUALIFIED PENS.

In accordance with the regulations the following pens, which failed to produce eggs of the required weight per dozen, will be returned to their owners. They are—

Section 1—Pen 43 (White Leghorns), R. Kerr, Longwood; weight, 22¾ozs.

Section 1—Pen 75 (White Leghorns), W. Purvis, Glanville; weight, 22¼ozs.

Section 2—Pen 115A (Black Orpington), Craig Bros., Hackney; weight, 22½ozs.

Section 2—Pen 119 (Silver Wyandottes), Tockington Park Poultry Farm, Grange; weight 23ozs.

The total eggs laid by these pens will be deducted from the grand total, and the test will proceed and conclude without any regard to these pens, which will not form any part of the records of the test.

BALAKLAVA WHEAT COMPETITION.

SECOND SEASON'S RESULTS.

By G. H. STEVENS, Manager Turretfield Experimental Farm.

The importance of wheat selection and the value of competitions of the nature of the one now in progress at Balaklava have long been recognised, but the Balaklava Branch of the Agricultural Bureau, acting in conjunction with the Balaklava and Dalkey Agricultural Society, was the first to act and to carry into effect such a competition.

The second year of the Balaklava competition was completed at last harvest. The conditions governing this competition were published previously, but we repeat them here for the convenience of readers and as a guide to those Branches of the Agricultural Bureau who may contemplate similar action.

Briefly stated, the conditions are—

Competition is open to any resident of the district within a radius of 15 miles of Balaklava township. Any variety of wheat may be grown, provided that it is a good average milling variety. The seed for the past year's sowing may be procured by the competitor from wherever he pleases, and from the crop produced must be selected the seed for the second year's sowing, and from the second year's crop the seed for the third year. The competition will extent over a period of three years. The cup, valued at £10 10s., offered through the Bureau, will be awarded to the competitor who grows the greatest quantity of wheat of one variety from a quarter-acre of land during the three years. The Agricultural Society offers the sum of £5 in two prizes—£3 and £2—for the highest and second highest yield respectively from the quarter-acre each year.

ALLOTMENT OF POINTS.

1. Yield (80).—One point awarded for every 20lbs. of wheat per acre.
2. Milling qualities (10).—A. Percentage yield of flour (5)—Based on weight per bushel to a large extent, the range to be considered from a milling point of view being from 57lbs. per bushel to 66lbs., as follows :—

lbs.		lbs.		lbs.		lbs.	
57	0·5	59½	1·75	62	3·0	64½	4·25
57½	0·75	60	2·0	62½	3·25	65	4·5
58	1·0	60½	2·25	63	3·5	65½	4·75
58½	1·25	61	2·5	63½	3·75	66	5·0
59	1·5	61½	2·75	64	4·0		

B. Color (2)—Based on past experience with samples of flour from the various varieties of wheat milled in the department, viz.—

Fair 0·5	Good 1·0	Very good 1·5	Excellent 2·0

C. Strength (3)—Calculated on same lines as color, taking a range of from 40 to 50, viz.—

40	0·5	42	1·0	44	1·5	46	2·0	48	2·5	50	3·0
41	0·75	43	1·25	45	1·75	47	2·25	49	2·75		

3. Purity of seed and type.—Based on notes taken at time of inspection of growing crop.

4. Weight per bushel.—One point for every pound above 60lbs. per bushel. Wheats weighing less than 60lbs. per bushel receiving no points under this heading.

RESULTS.

Appended is a table of the second year's results of the competition—

Competitor.	Variety.	Yield per Acre. b. lbs.	Yield. Max. 80.	Milling Qualities. Max. 10.	Purity of Seed and Type. Max. 5	Weight per Bushel. Max. 5.	Total Points Scored.
1 Twartz, H. L. ...	Bunyip	26 20	79·0	9·25	4·5	4·5	97·25
2 Thomas, T.	Yandilla King ..	20 42	62·2	8·25	4·0	5·0	79·45
3 Wagner, F. W. ..	Marshall's No. 3 .	20 22	61·2	6·75	5·0	3·0	75·95
4 Goldney, R. S. ..	King's Red......	19 24	58·4	6·25	5·0	5·0	74·65
5 Roediger, P. H...	College Eclipse ..	19 20	58·0	7·0	5·0	4·0	74·0
6 Roediger, P. H...	Yandilla King ..	18 48	56·8	7·5	4·5	3·5	72·3
7 Roediger, P. H...	King's Red......	18 36	55·8	5·75	4·5	4·5	70·55
8 Roediger, P. H...	King's White ...	16 22	49·2	5·0	4·5	3·25	61·95
9 Goldney, R. S. ..	Federation	16 4	48·4	7·0	3·5	3·0	61·9
10 Wagner, F. W. ..	Bunyip	15 22	46·2	7·0	5·0	0·25	58·45
11 Thomas, T. A. ..	Federation	14 49	44·9	7·0	3·0	3·25	57·15
12 Neville, K.	Marshall's No. 3 .	13 24	40·4	7·0	5·0	3·75	56·15
13 Neville, K.	King's White ...	14 24	43·4	4·75	5·0	2·5	55·16
14 Goldney, R.	Genoa	12 28	37·8	8·0	5·0	4·5	55·3
15 Neville, K.	Gluyas..........	13 44	41·4	5·25	4·5	2·0	53·15
16 Neville, K.	King's Red......	13 0	39·0	5·5	4·5	4·0	53·0
17 Thomas, T. A. ..	Marshall's No. 3 .	14 20	43·0	5·25	3·0	0·25	51·5
18 Kelly, H. J.	King's White ...	13 0	39·0	4·75	4·5	2·5	50.25

Last year the first three positions were held by King's White (O. L. Rosenberg) first, with a total of 95·1 points; King's White (K. Neville) second, with 87·05 points, and King's Red (O. L. Rosenberg) third, with 85·1 points. This year, however, the best these varieties could do was to gain fourth position (King's Red) with 74·65 points.

It is gratifying to note the success of such an excellent milling wheat as Bunyip, which scored the splendid total of 97·25 points out of a possible 100. This variety last year occupied fourth position on the competition list. The seed used on that occasion was imported direct from New South Wales, and it seems that after being grown for one season it has become more acclimatised, with a corresponding larger yield from the second year's crop. A yield of 26·20bush. per acre in an unfavorable season, as was generally experienced in the Balaklava district last year, is certainly very creditable, and should the third year's results be equally favorable, it would seem that there is a great future ahead of this variety in that district. Yandilla King (second) yielded 20·44bush., and Marshall's No. 3 (third), 20·24bush. per acre.

Generally speaking the season was not a favorable one in the district; indeed it was one of the worst experienced there for many years, the rainfall being over 3in. below the average, and 2in. below the precipitation of 1911. As a consequence the yields from the plots were not as high as one would expect in a fair average season, but considered in view of the rainfall, they show systematic, thorough cultivation by the several competitors. The following is the rainfall for the year 1912:—

	In.		In.
January	Nil	July	1·54
February	·29	August	1·48
March	·75	September	1·91
April	·40	October	1·51
May	·13	November	1·71
June	1·60	December	1·02

Total 12.34in.

It was pleasing to note the enthusiasm and interest displayed in the competition, which was as keen, if not keener, than when operations were first commenced. There were four new entries, but these could not compete for the cup, because the selection extends over three years. They were eligible, however, to win the Agricultural Society's prizes of £3 and £2 respectively, which are awarded every year for the two highest yields. These prizes were secured this year by Messrs. Twartz and Thomas.

The heaviest weight per bushel was Mr. R. S. Goldney's King's Red (65½lbs.), the highest last year being 65lbs.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, July 9th, there being present Messrs. A. M. Dawkins, J. Miller, Geo. Jeffrey, G. R. Laffer, W. G. Auld (President Vinegrowers' Association), T. H. Williams, C. E. Birks, F. Coleman, Col. Rowell, C.B., Professors Lowrie and Perkins, and G. G. Nicholls (Secretary).

APPOINTMENT OF OFFICERS.

Mr. Dawkins read a letter from the Minister of Agriculture, intimating that he had reappointed Messrs. Geo. Jeffrey, A. M. Dawkins, Col. Rowell, and the President of the Vinegrowers' Association as members for a further period of two years from July 1st. On the motion of Col. Rowell Mr. G. R. Laffer was elected Chairman and Mr. F. Coleman Vice-Chairman. In nominating Mr. Laffer, Col. Rowell, C.B., paid a merited tribute to the valuable services which his predecessor, Mr. A. M. Dawkins, had rendered in the position. Mr. J. Miller, in seconding, mentioned that Mr. Laffer, who had previously occupied the chair for a term, had the confidence of every member of the board. Mr. Laffer acknowledged the compliment, and extended a cordial welcome to Mr. W. G. Auld, who, as President of the Vinegrowers' Association, had succeeded Mr. G. F. Cleland.

HORSE-BREEDING SOCIETIES.

A suggestion was received from the Warcowie Branch that the nomination fee under the regulations governing the formation of horse-breeding societies should be reduced from four guineas to three guineas per mare, and that the number of mares to be served by one stallion should be limited to 70 instead of 80. Professor Lowrie pointed out that this could not be adopted. Under the scheme originally submitted by himself the number of mares was restricted to 70, but most of the farmers with whom he discussed the matter considered that it was too low. The nomination fee had to be governed by the funds of the society and the need for securing the services of a good stallion.

AGRICULTURAL TESTS, EYRE PENINSULA.

Relatively to the desire of the Shannon Branch that the Government should test some of the land in the vicinity of Minnipa Hill with superphosphates, wheat, and oats, the Minister wrote that it was too late to comply with the request this season, but it would be kept in mind for next season.

TREE-PLANTING ON RESERVES.

At the instance of Mr. Dawkins it was decided to ask the Minister to secure a report from the Conservator of Forests upon a request from the Yongala Vale Branch, that the reserves in the hundred of Belalie, adjoining sections 142, 143, and 180, should be planted with trees.

AUSTRALIAN FOREST LEAGUE.

Letters from the provisional committee of the South Australian Branch of the Australian Forest League were received. Members were fully in accord with the objects of the league, and the secretary was instructed to inform the secretary accordingly.

NEW BRANCHES.

Approval was given to the formation of new Branches of the Bureau at Parilla and Bandon, on the Brown's Well line, with the following gentlemen as members :—Parilla—Messrs. A. J. Stevens, H. G. Johnson, J. Roachock, G. Neindorf, M. Shannon, P. J. Brown, J. H. Daniel, G. Gregory, C. Millstead, P. Harrip, J. J. Foale, L. Shannon, J. Lee, T. Kerby, P. O'Driscoll, D. McPherson, P. Lewis, J. H. Dewhurst; Bandon—Messrs. W. Johns, J. D. Lee, W. Spurling, J. T. Corbett, R. Copp, P. Purdie, H. Cope, jun., W. H. Spurling, G. G. White, J. T. Retallack, C. A. Evans, L. Dohnt, H. Knowles, M. Walsh, G. Retallack, A. Dohse, W. Burdett, A. Purdie, L. R. Purdie, H. S. Cope, W. Johns, jun.

LIFE MEMBERS.

The following gentlemen were approved as life members of the Bureau, viz. :—Messrs. W. H. Hughes (Longwood), and Samuel Solly (Watervale).

NEW MEMBERS.

The following new members were approved at the Branches shown, viz. :—Yongala Vale—G. Keatley; Borrika—C. H. A. Tonkin, J. Wright; Mount Bryan East—E. S. Wilks, W. Campbell; Georgetown—J. Buchan, H. L. Saunders, E. B. Tucker, H. Tucker, W. Mackwood; Berri—J. Wack, V. Fowles; Hawker—W. A. Reid; Redhill—A. Dick; Salisbury—A. R. M. Basford, B. Rumball, F. J. Fleet; Shannon—R. Brown, P. Fitzgerald, H. Schmidt; Pine Forest—E. Hewett; Geranium—W. Morcom, F. Norton, sen., E. Nickols, W. G. Nickols, E. Winch; Millicent—J. B. Mitchell, T. W. Kealy; Blyth—F. Wiltshire, J. H. Pratt, A. D. Pedlar; Pinnaroo—J. Pitkin; Hookina—H. Huddleston, F. Stone; Yabmana—F. W. Beinke; Northfield—A. Lowe, J. Eisele; Wirrabara—L. S. Cobiac, H. Francis, W. Rooke; Yongala Vale—J. I'Anson; Elbow Hill—P. C. Wheeler; Hooper—F. Yates, D. Murphy, C. W. Shultz, J. Schultz; Strathalbyn—W. H. Cumming, F. M. Michelmore; Lyndoch—A. Threadgold; Uraidla and Summertown—J. McAskill, F. H. Stacey, G. Collett; Watervale—J. L. Broadbent, F. J. Mutton, J. Ward, sen.; Lameroo—O. W. Davidson,

E. F. Davidson, G. A. Martin; Morphett Vale—S. Pocock; Koppio—J. Liddy; Coonalpyn—J. J. Angel, D. T. Cronin; Davenport—G. Goldner; Willowie—A. Bull, A. G. Blight; Renmark—J. E. Smith; Pine Forest—I. Edwards; Paskeville—R. Petherick, A. Petherick; Yallunda—W. E. Rolland, W. Forrest, E. Walsh, W. Winstanley, R. B. Jenkins; Keith—A. V. Shannon, S. C. R. Hantke; Woodside—W. Rollbusch, A. J. McCarthy, H. Howell; Morchard—W. Keauschner; Meningie—L. D. Martin.

VINEYARD AND ORCHARD PRODUCTION, 1912-13.

A RECORD VINTAGE.

The Government Statist (Mr. L. H. Sholl, C.M.G.) has issued the official return of yields of the vineyards and orchards of the State for the past season. The figures relating to vineyards make particularly pleasant reading, as it is shown that there was a substantial increase in the acreage under cultivation and the yield, while the quantity of wine made established a record. Excluding gardens of less than one acre in extent, the yield of grapes was 42,605 tons, or 2·00 tons per acre of the vines of bearing age, compared with 34,591 tons, or 1·67 tons per acre for the previous season. A total of 24,853 tons were used for wine-making, the quantity of wine made amounting to 3,974,838galls. This exceeds the previous record vintage of 3,470,058galls in 1911 by 504,780galls. Of the quantity made, 1,722,008galls. will probably be distilled. A reference to the results of the last five vintages shows that approximately one-half of the total wine made has been used for distillation purposes. Of currants, 52,208cwts. were dried, being an increase of 5,513cwts. Raisins.—Sultanas, 16,575cwts., increase 1,832cwts; all other, 18,673cwts., decrease 1,235cwts.

STATEMENT OF AREA AND PRODUCTION OF VINEYARDS FOR THE FIVE SEASONS, 1908-9 TO 1912-13.

Seasons	Total Area (Bearing and not Bearing).	Grapes Gathered.		Wine made.	Currants Dried.	Raisins Dried.
		Total.	Average per acre of Bearing Age.			
	Acres.	Tons.	Tons.	Gallons.	Cwts.	Cwts.

EXPORTS OF WINE.

A substantial export trade in wine and brandy made from wine is carried on with the other Commonwealth States ; but as it is not recorded, the following statement is confined to the exports of wine to countries beyond the Commonwealth.

Wine.	Oversea Exports for Years—				
	1908.	1909.	1910.	1911.	1912.
Gallons	320,438	520,269	449,673	585,603	461,414
Value .... £	32,634	53,325	48,414	66,617	53,763

For the years 1908 and 1909 (the last two years for which complete inter-State records are available) the export to other States were respectively 440,088galls. and 525,409galls. Since 1909 it is estimated that the exports have ranged from 520,000galls. to 550,000galls. annually.

On this estimate the exports oversea and inter-State for 1912 were 1,011,414galls., with an average annually for the last five years of 978,579galls.

VALUE OF PRODUCTION.

The following statement shows the estimated value of vineyard production grapes for table, currants, raisins, and wine made) for the seasons 1908-9

to 1912-13 and the percentage of value to total value of all crops, and the average value per acre of vines of bearing age.

Seasons.	Total Value.	Value of Vineyard Production.	
		Percentage to Total Value of all Crops.	Value Yield per Acre of Vines of Bearing Age.

ORCHARDS.

ACREAGE.

The area under fruit culture has been steadily increasing during the last five years. The latest returns show that 23,905 acres are devoted to this purpose. Of this acreage the trees which have reached bearing age account for 16,875 acres ; and the trees which have not yet reached bearing age, 7,030 acres.

PRODUCTION.

In addition to the fruits mentioned below considerable quantities of berry and bush fruits are produced, also almonds and olives.

Kinds.	Seasons and Quantities of Fruit Produced.				
	1908-9.	1909-10.	1910-11.	1911-12.	1912-13.

GEO. QUINN, Inspector of Fertilisers.

THE WHEAT MARKET.

Under date London, July 4th, *Beerbohm's Corn Trade List* states, in regard to the wheat position — "The demand continues very quiet for wheat in all positions, and prices have declined 3d. to 6d. for practically all descriptions. There was rather a steadier tone at the close yesterday, and this may be attributed to the very unsatisfactory state of affairs in the Balkans. The crops are now ready to be harvested, and if the fighting continues it may be difficult to save them, with so many men engaged in the war and the consequent shortage of labor. Unless some of the other powers become involved, the effects of the war, so far as supplies of grain are concerned, will be mainly confined to the countries interested in the war. There is no particular change in the general situation. The weather has been favorable on the whole for the wheat crops in importing countries, and harvest is gradually extending in Italy and the south of France, so that the demand for foreign wheat continues small. The latest reports from Russia and Roumania are very favorable, and so far as the yields are concerned promise to be fully satisfactory. A good deal of rain, however, has fallen in South Russia, and if it continues for any length of time will affect the quality.

It will be seen by the tabular statement given below that there has been a very large decrease in the world's visible during June."

TO ADVERTISERS.

The "Journal of Agriculture" has a circulation of over 6,500 Copies monthly amongst the Cultivators of the Soil in South Australia, and consequently is a valuable medium for advertising Farm and Orchard Supplies and Requisites.

Particulars as to charges for space on application to the Department of Agriculture, Adelaide.

DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on August 1st—

Butter.—The butter and cream received during July increased in quantity. Local production, however, is still behind requirements, and values in factory butters are only a shade easier than a month ago. Best factory and creamery, fresh in prints, sold at 1s. 2d. to 1s. 3½d. per lb.; choice separators and dairies, 1s. 0½d. to 1s. 1½d.; store and collectors', 10½d. to 11½d. per lb.

Eggs.—The seasonable increase has set in, and with inter-State trade rather dull values have receded very considerably since the beginning of July. Guranteeed new-laid hen are 9¾d. per dozen; duck, 10½d.

Cheese.—Prices show an advance of about a halfpenny during the month owing to stocks running down. However, many factories are forwarding increasing quantities, and lower rates are therefore anticipated. Values—7¼d. to 7¾d. per lb. for large to loaf.

Honey.—There is a good demand for prime clear extracted at 3d. to 3¼d., but second grades are selling slowly at 1½d. to 2d.; beeswax is very saleable at 1s. 2d. to 1s. 2½d.

Almonds are being speedily placed at the advance lately established, viz., Brandis, 5¾d.; mixed soft shells, 5¼d.; hard shells, 3d.; kernels, 1s. 4d.

Bacon.—Supplies of bacon are still arriving from the east, as the shortage of live hogs in this State continues. The trade in sides and middles has tended to be a little dull, but this is only to be expected at this particular time of year. On the whole, fair quantities have been put through at—Best factory cured sides, 9½d. to 10d.; hams, cooked, 11d. to 1s.; uncooked, 9d. to 10d.; well cut and cured farm middles and rolls, 7d. to 8½d.

Live Poultry.—Increasing quantities have been submitted at our mart lately, the restrictions preventing the sale of poultry at the Adelaide live market having, no doubt, attracted consignments here; but as the demand has been exceptionally keen all lots have been readily cleared at prices showing an improvement on previous month's rates. Good table roosters realised 3s. to 3s. 7d. each; plump hens and nice-conditioned cockerels, 2s. to 2s. 6d., only a few coops of light and mixed sorts selling down to 1s. 6d. to 1s. 8d.; ducks, 2s. 9d. to 3s. 10d.; geese, 4s. to 5s.; pigeons, 7½d.; turkeys, from 7d. to 10d. per lb. live weight for fair to prime table birds.

Potatoes and Onions.—There have been heavy supplies of potatoes from Mount Gambier and Ballarat during the last month. The price of Victorians has eased considerably, but owing to the more reliable samples offering at Mount Gambier the latter market has so far managed to stand its ground. Onions.—Until recently the Adelaide market has been supplied from local sources, but a demand has now set in for Victorian and Mount Gambier onions, and consequently prices are on a firmer basis. Quotations—Potatoes.—Gambiers, £4 10s. per ton on trucks, Adelaide or Port; 5s. to 6s. 6d. per cwt. in the market. Onions—Gambiers, £7 10s. per ton on trucks, Adelaide or Port; 7s. 6d. to 8s. 6d. per cwt. in the market.

The General Manager of the Produce Department reports on August 1st—

Butter.—The supply of cream to hand last month was much larger than for the corresponding period last year, and was of first-class quality. It is also very pleasing to note that the quantity coming to hand is steadily increasing. There has not been much fluctuation in the price for the month, and the present quotations are—Superfine, 1s. 3d. per lb.; pure creamery, 1s. 2d. per lb.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

September 3rd and October 8th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Amyton, July 15.

(Average annual rainfall 11·82in.)

Present.—Messrs. T. O'Donoghue (chair), W. and H. K. Gum, S. Thomas, J. J. Cormack, A. J. Phillis, L. H. Mills, T. Ward, M. Corcoran, R. Brown, A. Crisp (Hon. Sec.), and two visitors.

Fowl Tick —Mr. Brown read a paper in which he drew attention to the loss which the poultry industry was sustaining through the ravages of the tick. Various means of destroying the pest had been suggested, such as dipping the fowls in a weak solution of sheep dip, or smearing them with a mixture of kerosine and oil. These were not effective, however, whilst the tick had access to the roosts He had noticed that the pests were unable to climb the sides of a glass bottle, and set about erecting a fowl house as follows :—He put props in the ground about 10ft. apart, and hung wires from rafters on these for the support of the hen roost. Bottles, neck downwards, with the bottoms knocked out were hung on these wires. The perches were then hung at the required height. The house could then be erected to the desired size. Plain and netting wires were put outside the props and then straw to protect the fowls from the weather. The perch should not touch any part of the house. He had secured very satisfactory results. Mr. Gum preferred all iron houses—old tyre iron being used for uprights and rafters; galvanized iron being bolted to this When tick got into a house of this kind, straw could be burned in it, which would effectively destroy them. Mr. Kitto recommended scalding the roosts with boiling soapsuds.

Arden Vale and Wyacca, July 14.

(Average annual rainfall, 16·65in.)

Present.—Messrs. J. H. Williss (chair), M. and O. Echert, J. Absalom, H. Liebich, P. A. Hannemann, E., J., and T. Klingberg, R. Paynter, O. E. Hannemann (Hon. Sec.), and six visitors.

Mustard.—In a short paper Mr. R. Paynter said mustard throve best on fallow : and whilst it was a good fodder, it was a pest in a crop to be cut for hay or harvested. The best means of ridding the land of it was to run horses on the stubble, burning it as soon as possible. The land should then be ploughed whilst dry and harrowed after every rain. Then, as the mustard grew, it should be fed off with sheep or cattle, and the plough or cultivator should go over it when it showed up green in the spring. It grew best when the rainfall was below the average. Mr. Echert thought that whilst this weed was troublesome in a crop for binding, it did not spoil the chaff for sale purposes in any way, and it was a good fodder. Members generally concurred.

Coomooroo, July 19.

(Average annual rainfall, 11in. to 12in.)

PRESENT.—Messrs. C. Berriman (chair), W. Robertson, J. Brown, G. B. Lillicrapp, H. E. Fisher, C. Phillis, E. Brice, R. Brice, W. M. Robertson (Hon. Sec.), and one visitor.

VETERINARY EXAMINATION OF STALLIONS.—Mr. W. Robertson contributed the following paper on this subject:—"The compulsory examination of stallions by a veterinary surgeon at the subsidised shows is a practice which has passed the experimental stage, and I think is recognised by most horseowners to be sound in principle and calculated to increase the usefulness of the horse, to improve his value, and to put the industry of horse-breeding on a more profitable basis by reducing the chances of loss from breeding an unsound animal. But there is one aspect of the question which so far has not received as much attention as it should. A considerable number of stallions which pass the veterinary test and are exhibited at the shows are partially or wholly useless for getting foals. This may be beyond the veterinary surgeon's power to detect, but some guarantee is required, either by records or otherwise, that the horse which takes a prize shall be capable of performing the service for which he was reared." Mr. J. Brown, in opening the discussion, said that owners of mares preferred to breed from a horse which had passed a veterinary examination. A horse might leave a good percentage one season and very few the next. This would depend to a certain extent on the health of the horse and the number of mares served. It was a great mistake to give a young horse too many mares, and also to have a stallion too fat. Mr. Lillicrapp said that one reason why many stallions did not leave foals was that they had too much work to do before they were fully matured. Mr. H. Fisher stated that a certificate of soundness was recognised as a guarantee, and enhanced the value of a stallion, and would be still better if he had a certificate as a sure foal getter. Four years he thought was the best age to begin to travel a horse, and he should not serve more than 35 mares for the first season. Mr. Bice considered that the mares should be examined as well as the horse. It was almost impossible to get some mares in foal. Mr. Berriman said that no horse should be travelled under four years of age, and should not have more than 40 mares to serve. At five or six years the number could be increased to 60. Some assurance should be given to owners of mares that a reasonable number of foals would be left. He condemned the practice of some farmers who insured the mares that were hard to get in foal and not those that were easy. To be fair to the man travelling the horse they should all be insured or none at all. Mr. Robertson, in reply, thought the fairest arrangement to both parties would be for part of the fee to be paid at the time of service and the balance when the mare had foaled. This system was in vogue with some horseowners in this district, and appeared to give every satisfaction.

Davenport, June 19.

(Average annual rainfall, 9in. to 10in.)

PRESENT.—Messrs. Roberts (chair), Bothwell, Holdsworth, Gosden, Messenger, Lecky (Hon. Sec.), and one visitor.

THE DAIRY COW.—Mr. A. W. Gosden read a paper on this subject. The success of dairy-farming, he said, depended to a considerable extent on the class of cow kept. In the North this matter did not receive the attention which its importance warranted. The Shorthorn, which had a world-wide reputation for hardiness and adaptability to climatic conditions was the most suitable breed. The herd could be improved by the use of a Shorthorn bull of a strain of known milking qualities on the best of the cows. Continuing, the paper read—"A better cross would be the one favored by the Government expert a few years ago for the Jersey cow, namely, an Ayrshire bull. It was found that Ayrshire bulls on Shorthorn cows brought about a better milking constitution, more active cattle, and an improvement in udder formation. The crossbred Jersey is an unprofitable beast for the butcher, but the Shorthorn cross sells well. Too much importance cannot be given the selection of a bull. He should come from a good milking strain, and the farther back his pedigree favors him in this respect the better his progeny are likely to be. Many favor the Shorthorn bull for the dairy herd because the calves are of more value as vealers. This is important to most dairymen, as they only keep a few calves to take the place of the cows that are getting too old to be profitable. It is generally acknowledged that the fifth and sixth years of a cow's life are the most profitable, yet if fed well and looked after she should yield a good return at 10 years. Denmark has always been held up to the world as the model and most successful dairy-farming country, and one would think its success might be due to the strict attention paid to cleanliness. This is an important factor, yet the very careful selection of only the best of cows to be kept as milkers—not only the best class or breed, but the very best milking strain—with the stringent and careful method of feeding go a long way toward accounting for the very high standard of Danish milk. If dairymen of Australia cannot follow a prescribed method of feeding cows we should at least get a good class of Shorthorn. With these and a little attention in feeding we should make dairy-farming a much more profitable industry than it is at present."

Hawker, July 15

(Average annual rainfall, 12 22in.)

PRESENT.—Messrs. G. H. Wright (chair), J. Palin, B. Manson, C W. Pumpa, W J. Pumpa, and J Smith (Hon. Sec.).

CARE OF HARNESS.—In a paper under this heading, Mr. J. Pyman said that owing to the different systems of tanning now adopted, leather produced at present was not equal to that of some years ago ; consequently, every attention should be paid by the farmer to his harness. On no account should it be thrown down on the ground, but hung in a dry shed when not in use Twice a year, at least, it should be thoroughly washed and dressed with neatsfoot oil. A good dressing for black harness could be made from 2lbs. mutton suet and 3lbs. beeswax, melted over a slow fire ; 4lbs sugar, 2lbs. lamp black, 2lbs. soft soap, and ½lb. indigo powder. When the whole had been thoroughly mixed, ½gall. of oil of turps should be added. If the harness were brown the lamp black and indigo powder could be left out. Copper rivets had their place as a means of repairing harness, but it was a mistake to put these in some places where stitching was necessary. Collars should be well fitting, and it was essential to hang them up when not in use. While there was little danger of sore shoulders when a hard, well-fitting collar was used, if the lining became broken it should receive immediate attention. It was better to put a pad above and below a sore than to cut a hole in the collar, but when this had to be resorted to it was advisable to sew the lining so that the body of the collar was kept firm.

Hookina, July 15.

(Average annual rainfall, 12in.)

PRESENT.—Messrs D. Madigan (chair), B. Sheridan, J. Carn, P. and T. Kelly, F. Stone, H. Huddleston, P. Kelly, jun., P. Henschke, S. Stone (Hon. Sec.), and two visitors.

FODDER CONSERVATION.—Mr. P. Kelly read a short paper as follows :—" Farmers in this district should not burn their stubble, but rake it up as soon as possible after the crop is off. It should then be stacked until required. When green feed is plentiful they should cut the best of it, such as wild oats, and especially that which grows in watercourses. This carted in and placed layer upon layer with straw makes good fodder. If fodder were collected every year in this way sufficient for a dry spell would be secured. I believe that black rust is caused by burning stubble every year." Mr Carn would put salt and molasses with straw. Mr. Sheridan did not think black rust was caused by burning stubble. [In this regard Mr. D. McAlpine (Government Vegetable Pathologist of Victoria) says—" It is sometimes recommended to burn the stubble in order to destroy any spores of rust that may be about, but as a matter of experience this has not been found to produce any appreciable difference. Theoretically, the burning of the surface of the soil should destroy a number of the spores, and to that extent is beneficial ; but, practically, the difference in the result is not marked. As far as most wheat soils are concerned here, the loss of vegetable matter is much more serious than any possible increase of rust."—ED.] When straw was raked, Mr. T. Kelly said, too much dust was gathered with it. He preferred cutting it with the binder. The Chairman recommended chaffed straw with bran and pollard for feeding during dry spells.

Morchard, June 14.

(Average annual rainfall, 11in. to 12in.)

PRESENT.—Messrs. E. J. Kitto (chair), W. Toop, W. Reichstein, E. D. Kirkland, W. A. Toop, H. Kupke, H. A. Toop, B. S. McCallum (Hon. Sec.), and two visitors.

NOXIOUS WEEDS.—In a paper under this heading Mr. G. Parsons drew attention to the necessity for destroying the star thistle. This commenced growth early in the winter, and frequently was not noticeable until flowering. The seeds were readily carried by sheep and other animals, and the plants rapidly increased in number. The most satisfacotry way of destroying it was to cut with a hoe when it was budding. A practice he had adopted was to go over the plants with a scythe two or three times at different periods, chopping under those with a hoe that were too short to be cut with the scythe. If this were carried out annually it would be found that the weed would be kept well under control. However, it was practically useless for one farmer to attempt to clear his land whilst his neighbor neglected it. Mr. W. Reichstein said it was little encouragement for the farmer to cut star thistles when the Government road adjoining his land was thick with this weed. Special mention was made of the stock road between Orroroo and Morchard. Mr. Kupke thought the councils should enforce the provisions of the Noxious Weeds Act.

Mount Remarkable, July 22.

(Average annual rainfall, 14·43in.)

Present.—Messrs. N. S. Giles (chair), L. A. Bauer, E. B. Andrews, G. Casley, W. Foot, R. G. Fiebig, G. H. Goddard, J. McIntosh, W. Oldland, F. B. Smith, E. M. Willington, J. Welsh, G. Yates, jun., T. S. Bishop, and H. H. Davie (Hon. Sec.).

Dry Farming.—Mr. J. Welsh read the following paper:—"There is a lot in the cultivation and harrowing of fallow, especially after rain, to keep the moisture in. After rain it is also good to harrow the growing crop as it is just appearing. This conserves the moisture for the young plant by retarding evaporation. Opinions are divided, however, as to the wisdom of harrowing the growing crop. Ground must never be so wet as to be boggy for this work. After a good rain feed off the fallow, as the rain starts all the weeds and rubbish to germinate. This year on the plain we have had no chance to do seeding after rain, as we have had no rain; yet we have plenty of time for a good crop if good rains and favorable weather occur toward late spring. For dry farming the land must be worked to a very fine tilth, and the seed sown shallow. On no account must the surface be left rough. I do not use manure. The soil, being in the dry area, is still very rich. I use Federation, Marshall's No. 3, and Yandilla King wheats, and these yield well. On my land the fallow need be ploughed only 3in. Heavier land would need only 4in. or 5in. In good seasons I have ploughed stubble, or even cultivated it, and have got results equally good with those off fallow. I still broadcast the seed." Members agreed that when the ground was fairly crumbly after rain, harrowing the young crop was good, and promoted strong vitality.

Orroroo, June 14.

(Average annual rainfall, 13·42in.)

Present.—Messrs. J B. McDougall (chair), E. Turley, J. M. Cadzow, J. J. Dennis, K. McLean, L. R. Cotterell, R. C. Sharp, W. W. Collins, J. C. Hagger, J. R Chapman, T. H. Tapscott, H. Chapman, A. L. Brice (Hon. Sec.), and two visitors.

Fruit Culture.—In a paper dealing with the growing of fruit in the North on small holdings, Mr. Hagger said it was necessary to plough land intended for this purpose to a fair depth. The harrows should follow, and then holes about 3ft. in diameter should be sunk to a depth of about 15in. These should be refilled with surface soil worked to a mellow condition. Rows should be not less than 12ft. apart. Strong trees with good leaf and wood buds and strong roots should be selected. They should be kept from the sun and wind during planting, and placed in the ground about 6in. or 8in., the holes then being filled to within 2in. of the surface. Damaged roots should be cut away with a sharp knife. The soil should be firmly trodden, without injuring the roots. Pruning should be fairly hard for the first year, to give the tree a good main trunk about 12in. to 18in. high. Three or four main arms should be cut to healthy outside wood buds. These should be situated at different levels on the trunk, or there might be a danger of the tree splitting in later years. A windbreak of tamarisk, tagosaste, or a double row of almonds should be provided. Apricots, peaches, Japanese plums, Cleopatra and Rome Beauty apples, Williams Bon Chretien pear, and Washington Navel or St. Michael oranges were recommended. Oranges required a good deal of attention. For the first two or three seasons they needed protection from winds and frosts. This could be provided by supporting bagging on three or four stakes driven in a short distance from the trees. The chief protection was necessary on the south-west side; the north-east aspect could be open. Plenty of water was required during summer and autumn. With the second winter's pruning of deciduous trees it was advisable to shape the secondary arms. The objective was a tree with a strong base, shaped like a cup, and opened in the centre, in order that light might have access to all parts. The tree should not be high enough to necessitate the use of a ladder for picking, spraying, or pruning. Saws and secateurs should be kept sharp and clean. A spray of arsenate of lead should be applied when the fruit was about the size of a pea, and this should be followed by two or three sprayings at intervals of five or six weeks. Hessian bandages, 3in. or 4in. wide, should be put round the tree trunks, as traps for the codlin moth. The soil surrounding the trunks should be well worked. When the fruit was about half size the trees should receive a thorough watering. All dead wood should be cut out, and shoots should be evenly spaced and not crowded.

Quorn, July 19.

(Average annual rainfall, 13·78in.)

Present.—Messrs. R. Thompson (chair), Britza, Shulze, McColl, Jago, Bury, Brewster, Noll, Cook, and Patten (Hon. Sec.).

Ensilage.—The following paper was read by Mr. Thompson :—"Ensilage is fast changing the methods of feeding every class of livestock. Employed in the first instance as feed for dairy cows, its use has spread until no big sheep farm is complete without a silo. It has also formed part of the feed, during times of scarcity, for horses ; but in this connection it has less to recommend it than is the case with almost every other class of stock. It has the merit of containing properties which are most desirable in feed. Generally speaking it is cheap, palatable, succulent, and bulky, and these are recommendations of no mean order. One of its chief advantages has been the effect it has had on the increase of the milk supply during the summer months in every dairy where it has been used. Such a succulent article of feed as ensilage cannot fail to be infinitely more desirable than dry hay or chaff fed without bran. Three Victorian farmers have recently thus expressed themselves on the advantages which have accrued to them since making a general practice of feeding with ensilage during the dry months. The first says that the increase of production of his milk and cream in the first year has more than paid for the cost of erecting his silo. His cows have been milked quite as freely and have given as good fat contents as if they were on green grass. The second says that ensilage has saved fully half the cost of feeding during the dry months, and has reduced the consumption of hay by fully half. The third pronounces ensilage as excellent for his dairy cows at all times of the year. Regardless of the nature of the seasons he makes use of his ensilage in conjunction with any other feed that may be available, and he considers that his cows gain materially in milk yield, as the quantity is increased, which, to his way of thinking is about the best possible evidence of the manner in which cows will respond to the juicy contents of ensilage. Where considerable quantities of bran are fed, the substitution of an ensilage ration keeps down the bran bill in an appreciable manner. Up to a certain point, depending upon whether production is extremely heavy or not, the more ensilage a cow eats the less bran will it be necessary to feed during the summer months. Besides the cost of the feed being reduced, there is also a reduction in the cost of producing a given amount of butter-fat. Only 50 cub. ft. are required for a ton of ensilage, whilst for hay fully 10 times as much space is needed. It certainly costs much less to put together 50 tons of ensilage than the same amount of hay. Where careful statistics have been kept regarding the cost per ton, the result works out as follows :—Hay costs 6s. per ton, and ensilage 2s. 6d. But generally speaking the average cost can be put down at 3s. per ton. Reference to the work done on some of the experimental stations in America shows that over a period of eight years the silos were filled at the average cost of 3s. 1d. per ton. This included cutting in the open, hauling, cutting up, trampling down, levelling, and covering. Moreover, the cost per ton, including seed, preparation of the land, interest on the investment, cultivation, cutting, and filling is figured out at 6s. per ton. In other words, the whole process of growing and conserving ensilage costs no more per ton than that of gathering hay. The advantages of ensilage may be summed up as follows :—It will keep young stock thrifty and growing at all times of the year, and enable the cows to produce milk and butter more economically ; it will increase the proportion of the milk and butter-fat, is more easily handled than dry fodder, and uses up and preserves in a palatable form material which would not otherwise be eaten. More stock can be kept on a given number of acres, and it is the most economical method of supplying feed for stock during the hot, dry periods of summer, when the feed in the open is both short and scarce. Experience has gone to prove that when feeding sheep with ensilage during the summer months, or during a period of drought, the best result can be obtained by giving a certain amount, say one-third of the quantity, of good wheaten hay. Sheep do not thrive so well on a succulent ration as on a combination of the dry and the succulent. Another feature in favor of ensilage is that if the silo be thoroughly airtight, the contents do not deteriorate in palatability with age, though, of course, there is a limit in this respect. Some astonishing results have been obtained from ensilage 10 or 12 years old ; but it is the exception o find anybody who can succeed in keeping either their pits or their silos securely locked up for such a time. Anybody who has the good fortune to look back 10 or 12 years without having to reckon two or three uncommonly dry summers in that period must consider himself fortunate." Mr. Noll had a stack of ensilage about five years old. Members generally agreed as to the wisdom of storing fodder in seasons of plenty

Tarcowie, July 15.

PRESENT.—Messrs. F. Sanders (chair), J. Brewer, A. Shrowder, M. McCarthy, J. Symons, D. Butterick, J. Dempster, W. Travers, C. Horlin, J. Burgess, T Ninnis, A. Dempster, and M. Murphy (Hon. Sec.).

FEEDING FOR MILK PRODUCTION AND MILKING.—In discussing the relative values of hay chaff and bran and cocky chaff and bran for feeding to dairy cows, Mr. T. Ninnis said his experience was that the latter produced a greater flow of milk, whilst the milk from cows fed on the former was richer in butter-fat content, but the bulk yielded was less. Although the balance of opinion was in favor of " clean stripping " when milking, Mr Symons held that the animal remained in milk longer if this were not done. Whilst the majority of members believed in milking the two fore, and then the two hind teats, others advised milking the off front and near hind, and then the near front and off hind.

Wepowie, July 18.

(Average annual rainfall, 13in. to 14in.)

PRESENT.—Messrs. C. Halliday (chair), C. Knauerhase, . E. and C. Pearce, G. Roocke, J. Crocker, T. F. Orrock (Hon. Sec.), and one visitor.

WATER SUPPLY.—In a paper on this subject Mr. T. E. Pearce said that where good holding ground was available a useful supply of water could be secured by constructing a dam, say, 40yds. x 30yds., x 10ft. deep, which would cost about £40. It could be taken out in four weeks if two teams were put on. Wells, however, were preferable, and where possible the services of an experienced wellsinker should be secured. The divining rod could be used to locate the supply and, if possible, the well should be sunk where the underground streams crossed. The use of a boring plant was advisable in rocky country, as the cost was less than that of manual labor. Mr. Roocke did not think the divining rod of service in locating underground springs, but other members thought it a splendid thing.

Willowie, June 18.

(Average annual rainfall, 11·90in.)

PRESENT.—Messrs. T. Hawke (chair), D McCallum, B. E. Schmidt, S. C. Greig, E. S. Bristow, S. Tucker, A. Gray, F. Richter, L. Hughes, W. P. Foulis (Hon. Sec.), and one visitor.

FARM MANAGEMENT.—Mr. T. Hawke read a paper, as follows :—" To the inexperienced, the notion that to manage a farm successfully necessitates any considerable possession of business acumen may seem a somewhat humorous proposition. It is astonishingly easy to demonstrate by figures how rapidly one may accumulate money by wheat-growing and other farming operations. Unfortunately, all who have had an intimate acquaintance with the practice of farming know that all theories and calculations are subject to considerable modifications and qualifications, and that the practice does not always work out in conformity with the theory. It is just here that the necessity for good management on sound business lines becomes evident. If it were possible to say with certainty that by fulfilling specific conditions definite results would follow, that is to say, if we could be sure that by adopting a certain form of cultivation, and using a given quantity of seed and manure, it were possible to accurately foretell the resulting harvest, there would be but little need for careful business management, and any man with health and strength, and sufficient capital to get a start on land, could confidently anticipate continued success. Observation, however, has shown that often where two men work on similar farms with similar opportunities and under similar conditions, one will fail while the other will succeed.

The difference has been mainly in the management. This has been very plainly demonstrated on Eyre's Peninsula during the past two years. Many new men, some young and some older, have ventured on the land in the confident hope of big returns, and not having had farming experience, and knowing but little, except in theory, of the thousand and one difficulties that they might expect to confront, have launched out in all directions and loaded themselves with liabilities, which, when the crops proved a partial failure, crushed them. However, throughout that great district are many who have worked under similar conditions and each year have consolidated their estates and improved their financial position. This subject is too bulky to treat in detail; so many avenues of thought are opened up when one thinks of all the departments of farm life where good management is essential, but I will try to indicate briefly some directions in which good management stands for success where the opposite would tend to failure. There are well-defined rules relating to farming that do not permit of any difference of opinion, such as, for example, the necessity for fallowing, the wisdom of conserving fodder for stock, the desirability of good sound fences, the need for up-to-date labor-saving implements, and the practicability of combining other side lines, such as sheep, dairying, and poultry, with wheat-growing. Then there are such things as the farm workshop, where simple iron, wood, and leather work may be done; and, again, the farm garden, where fruit and vegetables may be produced for use on the farm. But it is in the arrangement and carrying out of the various operations mentioned that the need for management occurs, and the one word that more nearly than any other sums up the position is—system. In farming, as in other callings, the absolute necessity exists for placing things in their true relative positions. First things must come first if success is to be achieved. The farmer who forgets that the main essential to success is fallowing, and who neglects this most important work to do a few little jobs about his workshop and thereby save a few shillings or even pounds in tradesmen's bills, is practising a false economy, and his management is faulty. That which applies to fallowing applies with equal force to all the other operations connected with wheat-growing. A good manager will not neglect to cultivate his land in the spring when the opportunity offers to kill rubbish for the sake of working his fruit garden, however much his inclinations may lean towards the latter. There are but 52 weeks in the year, and if all the side lines are to be touched upon and worked for profit, it means that a good deal of solid thought must be expended in order to prevent the less important work encroaching upon the time that should be occupied by the work that is more or most important. Then in regard to machinery and implements there is scope for plenty of foresight. How many farmers have purchased machines that appear right in theory, only to find that they became obsolete within a year or two, when something else had to be bought to do the work. As for conserving stock fodder, there is but one time when this work should be done, and that is whenever the food is available for conservation, and it is practicable to postpone other work. Only in this as in all else the good manager will evidence his personality by putting the fodder away in such form that it will be well protected from the weather, and can be opened up in good condition when required." Mr. B. E. Schmidt also read a paper on this subject. Carefulness in the matter of farm management, he said, was an essential; neglect meant the loss of both money and time. The homestead should be well and comfortably built. Stone walls should not be less than 10ft. in height, and iron walls 12ft.; a flat roof should on no account be put on. The horse stock should be well fed. Implements light of draught and up-to-date in every particular should be secured. Harness should be oiled at least once a year. A workshop, where small repairs could be effected, was indispensable. The person who intended commencing farming was recommended to gain some practical experience before he invested his capital, as there were frequently innumerable difficulties which did not meet the eye of the inexperienced man. In the discussion which followed, Mr. E. S. Bristow said pug walls involved too much labor in erection. Sparrows got into straw roofs, and the wind moved the straw so that in wet weather frequently they leaked. Galvanized iron was best for both the walls and the roofs of stables and sheds It was necessary to oil harness three times a year. Mr. Tucker thought the most serviceable shed was constructed of pug walls with an iron roof. Iron walls soon became damaged, and limestone was difficult to procure on the plains; this prevented the use of concrete. Mr. McCallum erected a pug wall shed many years ago, and it was still standing He made the pug around the site, and trampled it with horses. Vehicles kept in sheds with pug or stone walls did not require tiring so frequently as those kept in open or iron-walled sheds. The destruction of oats was becoming a serious matter in this district, on account of the number of seasons that had opened late. Mr. A. Gray considered concrete the best material for walls. Skilled labor was not required. The concrete was simply placed between boards bolted together in the shap of the required wall. Harness should be oiled regularly; and care should be taken when purchasing neatsfoot oil, to see that it was pure All sweat should be removed from the harness before the oil was applied to it. Mr. S. C. Greig thought neatsfoot oil caused the stitches in harness to rot. He used a mixture of mutton fat and neatsfoot oil. Mr. Hawke used a mixture of mutton fat, oil, and resin. Mr. B. E. Schmidt thought mutton fat collected dust.

Willowie, July 15.

(Average annual rainfall, 11·90in.)

PRESENT.—Messrs. T. Hawke (Chairman), D. McCallum, S. C. Greig, E. S. Bristow, S. Tucker, L. Hughes. A. Gray, A. R. Wilkin, E. J. Kentish, A. and J. Stone, W. P. Foulis (Hon. Sec.), and four visitors.

WEATHER FORECASTS.—Mr. E. J. Kentish contributed a lengthy paper on long distance weather predictions. Members were divided in opinion as to whether reliance could be placed on these forecasts, and as to the likelihood of the development of the science in future years. [We regret that we are unable to print this paper.—ED.]

Wirrabara, July 19.

(Average annual rainfall, 18·91in.)

PRESENT.—Messrs. J. Hollett (chair), E. J. Stevens, J. Fitzgerald, W. Bowman, C. F. H. Borgas, E. Pitman, P. Lawson, P. J. Curnow, H. Francis, C. Hollett, W Marner, E. Kavanagh, C. Hollett, W. H. Stevens, R. Curtiss, L. S. Cobiac, P. R. Hoskins, L. G. Dansie, A. R. Woodlands (Hon. Sec.), and two visitors

PLANNING THE FARM WORK.—Under the title "Systematic Farming," Mr. P. R. Hoskins read a paper in which he advised farmers and gardeners to plan out their work so that if it were found that they were getting behind with it, some of the less important duties could be left. He advised the following system as suitable for this district :—"At the beginning of January we should have the harvest and most of the wheat-carting completed, but possibly the latter may run into February. This finished, we can pay attention to such things as building stacks of straw in the paddocks for fodder and shelter for the stock, covering sheds and catching up odd jobs that have fallen in arrears during harvest time. In March we should clean the seed wheat, and, it advisable, pickle it at the same time ; it will then be ready for the field. Then there were stone-picking, cleaning the stable of manure, superphosphate-carting from railway, getting drills in order, harness oiled and mended, in readiness to start tilling the second week in April. By the end of April seeding should be in full swing, and with a drill doing 10 acres a day or 50 acres a week, this should be completed by the end of May. Drills should be well overhauled before being put away into the shed. Farmers should pay particular attention to cleaning out the super. box and give it a good brushing over with kerosine. During June, fence and clear land and get all necessary things ready for fallowing. Fallow during July and August. To finish fallowing by the end of August with an eight-horse team and a five-furrow plough will mean something like 35 acres a week for eight and a half weeks, which just cuts out the two months allotted. In September harrowing and cultivating should be done. In October shearing needs attention ; hay frames, binders, and harness should be got ready for hay-making. In November hay-cutting, stooking, and carting require attention, and possibly reaping. By December harvest is in full swing. It will be seen, when this plan is followed, that the horses are at work in January and February, then they have a spell. They are then engaged six weeks in seeding, are spelling during June, fallowing in July and August, spelling again during September and October, and should be in good condition to commence harvesting." Members generally approved of the suggested scheme, but thought modifications to suit weather conditions necessary

SYDNEY GRASS.—In reply to an inquiry as to the best method of destroying this grass, Mr P. J. Curnow said that on land that could be left idle for a number of years, arsenical scrub exterminators would be found effective. The Hon. Secretary thought these should not be used on account of their dangerous properties. For a small patch, covering for a time with galvanized iron would be found effective, but continual digging was advised for a larger area.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Booleroo Centre, July 11.

(Average annual rainfall, 15·83in.)

Present.—Messrs. W. Mitchell (chair), R. W. Stanton, R. Burrie, B. Reichstein, G. R. Hein, N. L. Brooks, W. H. Berrill, H. W. Kahl, W. H. Sanders, J. Carey, sen., J. M. Carey, J. and B. Kerr, H. C. Jaeschke, J. H. and J. Pepper, G. Ashby, W. H. Nottle, sen., W. Whibley, L. Fry, O. E. W. Bruns (Hon. Sec.).

Farm Horses.—In a paper dealing with the most suitable stamp of horse for the farm, Mr. H. C. Jaeschke said that in light sandy soil the walking was very heavy for a heavy horse, consequently one of a lighter stamp was preferable. In loamy soil, where the draught was greater, the heavier animal was better. For local conditions, as the land varied considerably he recommended the Clydesdales. However, the most important factor was attention to feeding and cleaning. Mr. W. H. Sanders also read a paper. When breeding horses, he said, the farmer should pay careful attention to the selection of the stallion and the mares. The former should be sound, compact, active, and of good temper. The unsound horse would be found to slacken in his work and bring the whole team back. Early foals were preferable, as they got a good start on the green feed. Good feed from the time of birth was of utmost importance. Horses should be worked in well-fitting collars. Rock salt should always be kept in the mangers. Members generally thought the horses in the district were of a good stamp.

Canowie Belt, July 15.

(Average annual rainfall, 20·04in.)

Present.—Messrs. E. T. Daly (chair), A. F. Dempsey, G. Kirk, R. Carter, H. A. Wedding, A. Noll, A. Sanderson, H. Schultz, F. J. Schultz, A. Spavin, J. Sparks, A. Kitschke, S. Crouch, C. O'Mahoney, E. W. Noll, C. J. Wedding, F. D. D. Stapley (Hon. Sec.), and two visitors.

Farm Management.—A comprehensive paper on this subject was contributed by one of the members. The first essential on the farm was a good fence, he said. A substantial six-wire fence, with two split gum posts and four tee iron droppers to the chain could be erected for about £35 per mile. He used the Donald wire strainer and kept the wires reasonably tight. This held the posts in line and doubled the life of the fence. Speaking of implements, there was a large variety of cultivators on the market, but nevertheless he thought the cultivator was the most imperfect implement on the farm. The use of the Λ cultivator was most common, both in set and stump-jump implements, and they tilled the land well, giving the least trouble to team and driver. The drawback was that they invariably bunched the soil in the centre of each cut, forming what was known as a crown, leaving only a light cut of loose soil on each wing. This undesirable class of work became intensified at each operation, until it caused even the plough to cut perhaps 2in. deeper at one time than at another; also when drilling, the seed was put in too deep in the crowns and scarcely covered in the wings. This caused irregular germination, and left both land and crop open to many hardships, especially on hillsides, where watercourses were formed by the ridging of the land. The zigzag shape of cultivator did not crown its land, but it left a number of unsightly open ridges in each cut, destroying all the principles of moisture conservation, and must prove disastrous on hillsides should a heavy fall of rain arrive before the land had been harrowed or levelled. The "one way disc" and the skim plough or cultivator, if skilfully driven, left a perfect seed bed, but they were cumbersome and difficult to handle, turning the soil all one way; they had to be worked around a land which was a disadvantage when cultivating in front of the drill. There was a challenge to implement makers to overcome the bunching of the soil by the Λ cultivator. The harrow was a very important implement. It was a mistake to have harrows made of heavy iron. Their own weight often broke the bulls and dulled the points. They should be made of mild steel bars, ⅜in. by 1in.; tines ½in. square, with points tempered hard. Harrow tines were usually pointed with one heat and then thrown down to cool. This made a very soft point, and a few days' work on hard, gritty land wore the points up to a blunt end. The land roller should be used much more frequently, especially in dry seasons; it consolidated the soil, giving the young plant a chance to fix its roots. A clod was more objectionable than a stone, because it absorbed moisture from the surrounding soil, but returned none, whereas the stone neither gave nor took moisture. He would use the roller then, if necessary, to obtain a firm seed bed. With the binder the effort to turn out very large sheaves overtaxed it, with the result that the tying parts were worn out while other parts were still as good as new. There was a great waste of hay in cutting 2in. to 3in. and even 4in. higher than necessary. A roller or leveller should be put over the land so that harvesting machinery might do its work properly and with safety. "Making hay while the sun shines" did not mean that cutting and stooking must be completed in the same hour. He would give it at least half a day's sun to wilt before stooking. The complete harvester was a great labor saver, and gathered the grain expeditiously, but it required careful handling or it would waste more than it saved The driver should be a man with presence of mind, and he needed a strong steady team of horses. Five good farm horses were necessary to keep a harvester travelling the regular pace for a season. The chaffcutter very soon saved its cost in the food value obtained in place of long hay, and the waste was reduced to a minimum. The seed grader was a machine that very few paid much attention to. Farmers were too careless and indifferent about seed wheat. They should carefully remove the seeds of all undesirable plants and aim at obtaining seed of the very best quality. The writer concluded by recommending farmers to drill seed in 3in. deep in dry seasons, particularly on well-worked fallow. The protection of implements, machinery, and harness from the effects of weather and from undue wear owing to neglect was urged as an essential part of the good management of the farm.

Breeding and Feeding Pigs.—A paper on this subject was also contributed. The writer favored the Berkshire-Poland cross, both for market and use on the farm. Sows must be kept in good condition, especially during the two months preceding farrowing. Plenty of clean slop feed, but not too thin, was recommended. It was doubtful whether pigs paid without milk in their ration, but it should not be given warm from the separator. For three-months-old pigs a little pollard should be mixed in the milk. For the first eight weeks they should be left with the sow, and she should be fed three times a day. Wheat or barley soaked in milk was to be recommended for the sow. He had yards for the pigs, but it did not pay to let them have a big run. He had sold eight-week-old pigs at £1 per head. When killing, he shot the pigs and then stuck them. They bled well and there was no struggling. The water for dipping should be ½gall. cold water to 4galls. boiling. If too big to dip, boiling water could be poured over the carcass. He added a handful of washing soda to a copperful of water. A big pig should be killed in the forenoon and left to hang until the next morning.

Gladstone, July 19.

(Average annual rainfall, 16in.)

Present.—Messrs. R. E. Lines (chair), R. Peters, A. Blesing, J. Eley, J. Sargent, W. Brayley, A. Anderson, F. Aughey, T. Mutter, F. Mutter, J. Fisher, W. L. Evans, H. Fay, J. Coe, R. Coe, G. Fisher, R. A. Humphris, J. Page, A. E. Dinning (Hon. Sec.), and two visitors.

Farm Implements.—Mr. W. L. Evans read a paper on this subject. All machinery with woodwork, he said, should be under cover for nine months of the year. Wood and iron sheds would be found most satisfactory, and these could be whitewashed with the following preparation :- -Fifty pounds of lime, over which boiling water should be poured, and then the following ingredients added, 25lbs. whiting, 5lbs. plaster of Paris, 3lbs. sugar, 2lbs. salt, 1lb. blue, ½pt. boiled oil. Continuing, the paper read —"It is well to keep all stock away from the shed, for they are apt to do damage or be injured. It is to be deplored that so many people allow poultry to roost on their vehicles and machinery, for nothing can be more horrible than to have to handle things on which poultry droppings abound, to say nothing of the lice that gets on one's clothes and body. A good plan is to sew together sufficient bags to cover each machine not in every day use. See that each machine is put in its place as soon as it is done with, but before doing so it is well to go round it and make a note of any parts needing repairs and fittings that are needed before it can be used again. See if any bolts are loose or lost, and so on. Having made note of everything, fasten it to the machine. This practice will save considerable time later on, and if the machine has to go to the smith for repairs, one can be fairly sure that nothing is missed. If this is left till the next season, important repairs will probably be forgotten. It is advisable in spare time to clean round all wearing parts and see that oil holes are free. Bearings may be broken unknown to the owner, with the result that accumulations of dirt and grease around the broken bearing end in the shafting being cut to pieces.

Go over every bolt and see that it is screwed tight. Paint such machines as binders, drills, or harvesters every two or three years. Wagons and drays especially should be painted, they being more often out in all weathers. Iron implements, perhaps, do not need cover, but they are all the better for a coat of paint occasionally to prevent rusting. In buying new implements or machines, every man will be guided by his own experience or fancy. We find one man swearing by a certain make of machine, and the next neighbor by another make, both claiming that their machine is best, and maybe it is, according to conditions and usage. In considering the various points in favor of any machine, one should always take into account the accessibility of each part. I have often spent an hour or more in trying to get at some part needing repair, while the actual job has only taken 10 minutes to do. Too much care cannot be taken of vehicles. The axles should always be kept well greased or oiled and properly washered up. If that were done their life would be considerably lengthened. Patent axles are more likely to have the washering neglected, as one has only to take off the cap and fill the reservoir with oil, and no thought is given to the back washers. Often have I seen vehicles taken into the shop with the axles either shining like mirrors or covered with dry, black powder, both denoting want of lubrication. Under those conditions the axle wears badly, the washers go, and there is a lot of play between axle and box, and this in turn has a very detrimental effect upon the wheels, especially those known as sarven. If the tires are at all loose, they should be cut and shut as soon as possible, otherwise the wheels will get out of repair." The following is also extracted :—" Many members advocate having a forge and accessories for farm use, and no doubt they are useful at times. But I think you will agree with me that the man who can handle all the tools recommended in some papers would have but little time to till his land and care for his stock. Nevertheless it is well to have a few tools about the place in case of emergency ; but only temporary repairs should be effected, leaving the proper fixing up for the tradesman. Such things as S hooks and eyebolts can be made at home. They are done for cheapness, but would farmers take from a tradesman the same class of work that they turn out at home ? I fear not. If they would they could probably get them at half the present cost. By all means have a forge and anvil and a few other tools, and take care of them. My experience is that on farms tools are left about just where they are used last. Good saws in damp places, planes likewise, a brace here, and bits in some other place. This sort of thing goes to show that the farmer has not time to handle tools properly, and therefore the purchase of expensive tools is only a waste of money." Members were divided in opinion as to the advisableness of the farmer's son spending 12 months in a blacksmith's shop. Mr. Brayley urged farmers to carefully note any repairs necessary to their implements at the end of the season. He preferred neatsfoot oil for use on binders. Mr. Eley recommended castor oil for screwing, and separator oil for other purposes.

Georgetown, July 19.

(Average annual rainfall, 18·32in.)

Present.—Messrs. J. Myatt (chair), A. Smallacombe, E. Hewitt, J. Buchan, M. J. McAuley, M. B Saunders, A. Erickson, and S. Eyre (Hon. Sec.).

Sheep on the Farm.—In a short paper on this subject, Mr. A. Smallacombe said that although this district was an ideal one for wheat-growing, the farmer was well advised to keep sheep. Not only would these provide him with his meat supply, but the assistance they rendered in clearing the fallow was of the utmost importance. They should be put on immediately the weeds appeared, and kept there until the cultivator was put over the land. Merinos were generally favored, but the higher lambing percentage secured from crossbred ewes, and the fact that the lambs of the latter matured earlier, weighed heavily in their favor. The value of the fleece, lambs, and general hardiness of sheep made them most preferable for the farmer. Members generally thought the lamb trade of little use to farmers unless they were situated in favored spots. The Merino was preferred for the farm.

Julia, June 19.

(Average annual rainfall, 18in. to 19in.)

Present.—Messrs. T. Prior (chair), C. Nash, A. Pfitzner, W. Hall, B. J. Schmidt, W. Thiele, G. Gaerth, J. T. Freeman, E. Richards, T. Brown, T. Neylon, and W H. Neal (Hon. Sec.).

Fallowing.—Mr. W. Hall read a paper on fallowing. "Fallowing should be started as soon after seeding as possible," he said. "It is not a good practice to give the team a fortnight or three weeks' spell, as a few weeks dry weather would throw back the work. In my opinion a much better return may be secured from early fallow than from late. The ground should be ploughed 4in. or 5in. deep if it will stand it. Clay is, of course, much better left where it is. Harrow as soon as possible after ploughing, as after it has been exposed to the air for only a few days the soil has a tendency to crumble, and it does not take so much labor to get it into a fine condition as it would if left lying a while. If left, there may be a lot of rain and the soil may get baked down so hard that harrowing will do very little good. I do not think it advisable to commence cultivating very early in the season, or there may be a great deal of rubbish to kill afterwards.' Sheep will see that not much goes to seed. After cultivating, leave the fallow until after rain and then harrow again. I do not think one can harrow the fallow too much after rain in this district." Mr. Prior thought it a good plan when fallowing to stir up the subsoil with a hook, but care must be taken not to turn it on top. In one instance he ploughed very deeply and the subsoil crust was broken. On this piece of land he had a much better crop than from other parts of the farm. Mr. Thiele thought it better to leave fallow lying open a month before harrowing.

North Booborowie, July 16.

(Average annual rainfall, 16·35in.)

Present.—Messrs. W. B. Ashby (chair), W. R. Birt, M. Canny, L. D. Clark, W. E. Hannaford, P. McColive, E. J. Morgan, F. L. Phillips, K. Phillips, J. W. Smart, A. S. Tall, W. C. Warner, and A. V. Simpson (Hon Sec.).

Fencing.—A paper, as follows, was read by Mr. L. D. Clark :—"It is well to bear in mind that a good fence really costs little more than a bad one. Some fences one sees are veritable traps for stock, and many valuable animals are ruined through getting entangled in barbed wire loosely hung on the posts. Then, again, bad fences are often the cause of ill feeling among neighbors. Where sheep are kept it is advisable to put in five plain wires with one barb (12 gauge) on top. No 8 black iron wire will be found the best, as it is not so apt to break as galvanized or steel wire. The strainers should not be more than seven chains apart, as where there is a long strain it is difficult to keep the wires tight. One wooden post should be put in every chain, and five T iron posts between the wooden. The former should be 5ft. 4in. long, and put in the ground 20in., leaving posts 3ft. 8in. high; 4ft. 6in. will be long enough for iron posts. Strainers should be in the ground about 3ft., and 4ft. high, and those at angles and at the end of the line should be well strutted. The first wire should be 6in. from the ground, second 1ft., third 1ft. 7in., fourth 2ft. 3in., fifth 2ft. 11in., and top wire 3ft. 8in. First put up the strainers and wooden posts and bore them, and then run out the barb wire. Strain and fasten it to the wooden posts, which are to be bored 2in. from the top for that purpose. The iron posts can then be driven in and the barb wire fastened on with No. 12 wire. The plain wire is then run in, for which a jenny or reel is used." The writer then described the method of making a jenny. Mr. Hannaford preferred a fence as follows:—Five bottom wires No. 8 gauge, with top wire of No. 12 barb, spaced as follows from the ground—Bottom wire 6in., next 6in. higher, third 6in. higher, fourth 6in. higher, fifth 7in. higher, and barb 9in. higher, making the height of the fence 3ft. 4in. Strainers from nine to10 chains apart, 3ft. in ground, and standing 2in. over barb (thus requiring to be 6ft. 6in. long), strutted at the angles with good long struts sawn square at head and carefully fitted into the strainer between the third and fourth wires, the other end being beamed on a stone solidly rammed into the ground. Posts 60ft. apart sunk from 20in. to 23in. in ground, five flat iron standards between posts. Mr. Morgan did not think Mr. Clark's method of putting the barb on first a good one. He pulled the bottom wire through the posts first to align the droppers, and put the barb on last. Differences of opinion were expressed regarding the spacing of the bottom wires. Mr. Birks thought it should be 4in from the ground, there then being a space of 5in. to the second wire and 6in. to the third, in order to keep in crossbred sheep and their lambs. Mr. Ashby was of opinion that the fence described by Mr. Clark was suitable for Merinos, but British breeds of sheep should be kept in specially netted paddocks.

Port Broughton, July 25.

(Average annual rainfall, 14·44in.)

Present.—Messrs G Pattingale (chair), W. Whittaker, T. Pattingale, J. Hoar, E. Allchurch, G. Routley, and J. H. Fletcher (Hon. Sec.).

Breeding and Management of Cows.—The Hon. Secretary presented a comprehensive report of a lecture given by Mr. P. H. Suter, Government Dairy Expert, at the Pine Forest annual meeting on August 15th In the discussion which followed, the Chairman said that his experience had proved the bull to be more than half the herd. The main trouble with bulls was that they would go over the fences to neighbors' stock. Mongrels were not such bad fencers, and this fact accounted to some degree for the few good bulls kept. Mr. Whittaker thought much could be done by co-operation to secure first-class bulls.

Port Germein, July 19.

(Average annual rainfall, 12·84in.)

Present.—Messrs. Hacket (chair), Carmichael, Head, Deer, Stone, Pearce, Teasdale, Crittenden, Holman, Glasson, and Stewart (Hon. Sec.).

Conservation of Fodder.—Mr. F. Glasson read a paper on this subject. He urged the need of providing in years of plenty for less bountiful seasons. Hay should be thatched to prevent waste, and should be taken out of the stack clean to the ground, not allowing quantities to be destroyed round the stack. He would bind some of the crop and put it through the header, chaffing the straw with hay for stock. Cocky chaff and straw should also be saved for bad times. Members agreed generally, but were divided in opinion as to value of headed or thrashed straw.

Comparison of Seasons.—Mr. A. Carmichael gave some interesting statistics of rainfalls in past years, and said that some of these had convinced him of the need to conserve a good quantity of feed. The year most nearly comparable with this was 1886; the figures are given below—

	Rainfall, 1886.	Rainfall. 1913.
January	nil	nil
February	0·10	0·50
March	nil	0·64
April	0·50	0·02
May	1·25	1·00
June	nil	0·47
July	0·85	0·46
Total for seven months	2·70	To date (19/7/13) 3·09

Mr. Carmichael's paper concluded—"Thus we still have a chance, should good rains fall shortly, to have plenty of feed and a good harvest if we can only have patience to wait. I do not agree with those who say, whatever rain falls it can do no good."

Port Pirie, July 5.

(Average annual rainfall, 13·21in.)

Present.—Messrs. J. Greig (chair), W. Munday, H. G Hawkins, C. E. Birks, T. G. Kirchner, W. R. Wright, E. J. Eagle, E J. Hector, F. Johns, D. L. McEwin, and A M. Lawrie (Hon. Sec.)

Cost of Farming in Pirie District.—Mr. H. G Hawkins read a paper as follows:—"I will take a farm of about 800 acres, and assume that it is an improved one. The improvements should include a well-built house suited to the needs of the size of the family. The homestead should be near the centre, with a good water supply. All outbuildings should be built of stone, if procurable, and roofed with iron. There should be a stable for 12 horses, with two loose boxes for light horses, chaff shed, and engine-room attached, and a good stock yard and crush pen erected with post and rails about 6ft. high. A hay yard on the opposite side of the stable, or at the back of it, and a good hay shed close to the cutter will be found a great convenience. There should be a small cow yard with shed and bails not too far from the house. An implement shed large enough to hold all the farm plant, and a sparrow-proof trap shed. The barn should be very carefully built, mice-proof, with the floor about the height of the bottom of the wagon. A man's room, blacksmith shop, fowl run and sheds, and pigstye are required. The farm should be well fenced with six wires, and divided into convenient paddocks of about 100 acres in size. All should be divided from the homestead by good strong gates. The above may be called model improvements. The working plant is the real essential. Where it is proposed to crop about 350 acres and to fallow 350 acres each year, 12 good draught horses will be required, which will on an average cost £35 each, and two light horses

£20 each, the total outlay for horseflesh being £460. In addition, a six-furrow plough (£38), 15-tine cultivator (£32), 15-hoe drill (£42), set of six harrows (£12), binder (£38), two harvesters (£170), wagon and frame (£70), heavy tip dray (£25), spring dray (£18), trap (£40), horse rake (£10), grader (£25), chaff-cutting plant (£140), wagon harness, consisting of six spiders and two saddles (£12 10s), 12 sets of harness (£24), plough chains and swings (£8), set of trap harness (£8), spring dray harness (£6), riding bridle and saddle (£5 10s.), and tools for blacksmith shop (£20), will be required. Two milking cows will supply milk and butter for the house, these will cost £12 ; 50 fowls, £3 10s. ; and two pigs, £1 10s. If the farm is situated in a fairly good feed district, and only two or three foals are reared per year to keep up the number of working horses, also only a few young cattle kept, a fair amount of feed will be available, and I advise keeping as many sheep as possible, say about 150, which will cost £85. The total outlay is thus £1,070, including £70 for furniture. It will be necessary to take into consideration the first year's hay supply, &c. Forty tons will cost £100 ; 110 bags of seed wheat, £55 ; 9 tons of super.. £38 ; council rates, water rates, and land tax will involve £35 ; repairs to fences, &c.. £20 ; breakages and small items such as bluestone, £10 ; wages for one man for 12 months will amount to £70, and his keep £25 ; with living expenses for the farmer's family for 12 months, say, £100 ; for 1,500 new bags, binder twine, sewing twine, oil, £58 will be needed—making a total outlay of £511. The farm will cost at least £5,000, and interest on this amount at 5 per cent. will equal £250, and interest on the £1,070 invested in plant, £53, a total of £303, with the £511 expenses, making a grand total of £814. For 1,500 bags of wheat at 10s. per bag, £750 will be received, and for wool £40 in addition to £10 from other sources, making a total income of £800, or £14 below the outgoings, and no account taken of depreciation of plant, &c. The above estimate is based on the first year's working, the plant purchased being new, and a 15bush. average harvest being assumed. The cost for hay, &c., would not be quite so much when grown by the farmer, but it could be sold at market rates if not kept for use. Such an outlay is not necessary for the first year's operations Portions of the requirements could be acquired gradually, and might be bought for less second hand, but the repairs, &c., would be higher, and these would need to be replaced much sooner." Mr. Munday thought that Mr. Hawkin's paper dealt with a rather up-to-date farm, and that money at the present time could be far better invested in other ways. He agreed with the estimated cost of plant and working of farm. Farming was not so profitable as some people thought. Mr. McEwin also agreed. If anything, Mr. Hawkins estimated too little for harness. Mr Birks thought that if less land were cropped each year, and a few more stock kept the income would be as large or probably larger. He did not believe that farming was as bright as some people thought.

Redhill, July 15.

(Average annual rainfall, 16·79in.)

PRESENT.—Messrs. J. A. McAvaney (chair), Cox, Coffey, Lines, Potts, E. and B. Steele, Button, Pengilly, Kelly, Campbell, F. and F. A. Wheaton (Hon. Sec), and two visitors.

FENCING.—Mr. Lines read a paper on this subject. As gum posts would be expensive in this district, he recommended for a ring fence the use of myall posts, costing about 1s. each on the farm if not too distant from the railway, and three tee iron posts in between, the distance apart being 9ft. He would have two barbs, the top one being heavy and the next rather lighter, and would make the fence rabbit-proof from the start. The bottom wire might be 6in. from the ground, to allow plenty of space for drifting soil. The top wire should be strained up first. A good discussion followed. Some members preferred all irons, others five to seven irons between the wood posts, while the general opinion was that a wood post should be placed at regular intervals outside the fence and fastened to an iron. Mr. F. Wheaton considered it best to have two barbs, but the second barb he would place as the third wire down. Mr. Coffey would have a uniform type of fence all over the farm to facilitate valuation.

FARM MANAGEMENT.—Mr. B. Steele read a paper on this subject, and at the outset said that the appearance of the farm was an indication of the owner's management generally. Loose hay around the stacks should be raked up to avoid waste. In building a stable it was important to divide it into 5ft. stalls, so that every horse would get his share of feed. Horses in work should be cleaned down every morning and again at the dinner hour. They were then less liable to sore shoulders. It was a mistake to connect too many buildings, because of the risk of loss in case of fire. Fences would be less damaged if the land were not cultivated within 3ft. This was particularly important where a large number of iron standards and droppers were used. In throwing out the furrow when fallowing, it was a mistake to work the same way each year. If the start were reversed every year, instead of having hollows, the land would remain level, and at hay time a much more even cut could be obtained by the binder from the headlands. In discussing the paper, some members considered it unnecessary to allow as much as 5ft. for each horse in the stable. Others thought it necessary to plough as near to the fence as possible, to keep down the weeds. Mr. Lines preferred a two-storied stable, and the Hon. Secretary considered that a fowl-yard should be properly fenced off to prevent the poultry from travelling all over the farm buildings.

Spalding, June 20.

(Average annual rainfall, 20·25in.)

PRESENT.—Messrs. E. E. Gill (chair), D. J. Campbell, D. Shane, D. J. McAskill, G. Thorn, T. J. Preiss, J. Preiss, F. G. Saunders, H. Heithersay, S. Hennessy, J. Marron, P. Kelly, and D. A. Campbell (Hon. Sec.).

TREE CULTURE.—Mr. E. E. Gill read the following paper —" In presenting this paper on afforestation I would like to point out the great value of trees on a farm, first as a breakwind for the homestead and garden, second as a shelter for stock against hot and cold winds and the sun in summer, third as a supply for fencing and firewood, and fourth as an improvement in the general appearance of the farm. The trees most suitable for this district are sugar and red gums, Remarkable and Aleppo pines, pepper trees, white cedar, white acacia, and the swamp oak of New South Wales. Well-worked fallow is preferable to holes for planting. The best time to plant is early in the winter. This gives the tree a chance to become established before the dry summer sets in. Frost has no effect on pines, which should be tied firmly to small stakes. Deciduous trees should be planted as soon as they have shed their leaves. Sugar gums and pepper trees will be affected by frost unless protected. To do this, cut a super. bag in two, putting half the bag around one tree, and keeping it spread with three or four sticks. This extra work at planting time will save a lot of watering in late spring and summer. Leave the bags around the trees until November. When planting use an ordinary digging fork, and work the ground well. Care must be taken to spread the roots. This gives the tree a good hold of the ground, and the roots procure moisture from a greater area. If bamboos are used they must be covered at least 2in. and the earth pressed firmly around them. Plant all trees 8ft. apart each way. If they all grow, thinning is easy after three or four years, and the trees cut out make firewood. The great secret of success is keeping the ground loose around the tree after every rain or watering. I believe in watering where possible if the spring is dry, but trees that are alive at New Year will nearly always live without any more watering. With the foregoing methods I have had very good results. Out of 1,500 trees planted last winter over 1,300 are living. Sugar gums first grown in pots and planted out last July are over 6ft. high, and some first grown in bamboos are 4ft. high. Open root red and blue gums are also 4ft. high. These were all protected against frost. For shelter around a garden, gum trees must be planted at least 85ft. from the garden. Pines and peppers can be planted within 30ft. without causing trouble. The Aleppo pine, although not so beautiful, will grow in poorer soil and on a lighter rainfall than the Remarkable, and it is not so likely to die at four or five years. Light ploughing between the trees every year will more than repay the cost, as it conserves the moisture. Trees will often do well for three or four years on a limestone subsoil, but those on ground with a good clay subsoil will usually do better after reaching that age. A good method of watering young trees is to hoe a trench around each tree, and into this put about 4galls. of water. During the next day dig the earth back around the tree. This keeps the water where desired, and digging the earth back again destroys the cracks and leaves the ground loose." Mr. G. Thorn also read a paper. While there were no natural forests in this district, he said, different varieties of the eucalyptus family did well. South Australia was noted for the rapidity with which its trees grew. Continuing, the paper read :—" The time for planting all varieties of pines, white cedar, white acacia, plane trees, willows, firs, is early in the winter, so that the young trees will get the full advantage of the rain. Gums must be protected from the frosts. This entails a good deal of work, and an easier plan is to order trees in tubes and leave them in a case well packed together in a sheltered spot, taking care to water them when necessary. Prepare the ground by ploughing to a depth of 6in. or 7in., and allow it to lie in the rough until the end of August. Then harrow it down after a rain and conserve as much moisture as is possible. Plant the trees out the first week in October. Put them in the ground as deep as possible and leave only an inch from the ground to the first leaves. Put the earth in firmly around the bamboo to exclude all air, and leave it loose on the surface. If the weather remain dry, hoe a trench around each tree, but not touching the tree, sufficient to hold 3galls. or 4galls. of water. Then pour in the water, and next morning hoe the trench in again, but never touch the ground whilst it is in a boggy condition, and do not allow it to become too dry before hoeing. Usually three to four waterings are sufficient for gum trees. The distance between the trees depends on the objective. If straight timber for rails, &c., is required, it is advisable to plant from 6ft., 8ft., to 10ft. apart, but if planting for shade and shelter and general appearance, plant from 15ft. to 20ft. apart. The Remarkable pines in the Angaston Recreation Park are about a chain apart, and are just about the right distance. The trees in the fine avenue of Moreton Bay figs along the bank of the river in Gawler are somewhat closer, and ultimately they will injure one another. A tree must have room to develop. The most deadly enemy of the young gum trees is certainly the frost that is encountered almost every year. Sometimes a tree will be killed in its third year, and it is practically impossible to guard against this. Rabbits and hares are both very destructive, therefore it is most important to wire net around the trees. Cattle also are mischievous if they get into a plantation. A good strong fence is a necessity. Grasshoppers and caterpillars will destroy the young trees. These cannot be effectively guarded against. Undoubtedly it is a good idea to plant an area—say of half an acre—either oblong or square, in each paddock, chosing the best of the land for this purpose, to act for shade in the summer and shelter in the winter. If sheep get adequate shade from the fierce sun, from a farthing to a penny per pound more would be secured for the wool. With reference to the more ornamental trees, the sterculias stand very high in public estimation, and rightly, too, for they are highly ornamental. One variety of these, called the flame tree, is a fine sight while in flower. Another variety is commonly called the Kurrajong. I can recommend the Nerium family on account of the splendid growth made by these in the district. The tagasaste is very suitable for hedges, being a fast grower and very hardy. It is my earnest desire that each landowner will take immediate steps to plant a few hundred trees this season, and by doing so not only increase the selling value of the properties, but make the place a more desirable one in which to live, and quite possibly increase our annual rainfall."

Spalding, July 18.

(Average annual rainfall, 20·25in.)

PRESENT.—Messrs. T. J. Preiss (chair), Thorn, S. Hennessy, J. J. Gale, P. E. Kelly, P. N. Neill, A. B. Jones, J. Pluckrose, W. M. Summerville, J. Marron, A. J. Howley, T. Walsh, and D. A. Campbell (Hon. Sec.).

WOOL-CLASSING ON THE FARM.—Mr. F. M. Richardson read an interesting paper on this subject. The farmer with a few sheep, he said, suffered a greater loss proportionately than the large sheepowner through carelessness in preparing wool for market. There was no need to pay a skilled man to class farmers' wool, for a little care and the exercise of common sense was all that was necessary. The best prices could not be expected when different kinds of wool were bundled together, or Merino and crossbred were mixed in the same bales. Similarly the inclusion of dirt, chaff, &c., in the bales, loose packing, or other evidences of lack of care inevitably lowered the price commanded. The paper then continued :—" The shearing must be done on a clean floor, or the wool will become dirty. As it is of the utmost importance to favorably impress buyers, all fleeces should be skirted regularly, not necessarily deeply. In many cases only the dirty edges need be taken off. In other lots, such as wools of very light condition, it may pay to skirt off all the burry pieces. The fleeces should be rolled neatly from breech to shoulder, and they must never be tied with string. In cases where Merino and crossbred sheep are kept, it is advisable to shear them apart, so that the wool from each lot can be kept entirely separate. Heavy, matted, or discolored fleeces should be broken up and mixed with the skirts. It is well to pack bellies, pieces, locks, and stains separately, even if they have to be packed in bags, for mixed lots seldom bring their full value. The bales should be branded legibly with the name of the farm or owner, as insufficient branding often leads to trouble. They should not be too heavy, and should be numbered consecutively from the first to the last of the clip."

Yongala Vale, July 14.

(Average annual rainfall, 13in. to 14in.)

PRESENT.—Messrs. T. Keatley (chair), T. Battersby, C. and E. Fowler, E. Cooper, J. Barker, F. Laubsch, G. I'Anson, B. Webb, G. H. Jansen (Hon. Sec.), and one visitor.

HANDLING WHEAT IN BULK.—In a paper dealing with this subject, Mr. Battersby said he was unable to see where the farmers would gain any advantage with the introduction of the system of bulk handling of wheat. The suggestion that they would only have to purchase sufficient wheat sacks for two or three days' stripping meant that they would have to stop their harvesters whilst the wheat gathered into these bags was carted to the station. The cost of handling the wheat in bulk would be greater than that involved in the present system, and the cost of erecting elevators would be very heavy. The countries where the bulk system was at present being successfully worked were those in which the prices of material and labor were much lower than in Australia.

IMPLEMENTS AND MACHINERY.—Dealing with this subject in a paper, Mr. E. Fowler said the average farmer required a shed of at least 60ft. x 22ft. to afford due protection for his implements. Iron was preferable for roofing, as there was no danger from fire. At the end of the year all the machinery and implements should be overhauled, nuts being tightened, and all working parts oiled. When harvesters were stored a prop under the off side of the comb would have the effect of relieving the rack of portion of the weight, and thus obviating the tendency of the off side to dip deeper into the crop than the near side of the comb. All the woodwork should be painted yearly. Drill wheels should be periodically attended to, and ploughs and cultivators should be kept under cover. Broken castings should be renewed immediately.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Balaklava, July 12.

(Average annual rainfall, 16·03in.)

PRESENT.—Messrs. H. L. Twartz (chair), E. Fisher, R. S. Goldney, G. C. Neville, H. P. Burden, H. M. Tuck, A. P. Anderson, J. Spillane, L. Hoepner, O. Upill, W. J Gleeson, R L. Butler, B. R Banyer (Hon. Sec.), and one visitor.

SHEEP ON THE FARM.—Mr. Spillane said, in a paper on this subject, that the smallest farmer should not neglect to keep a few sheep. In addition to providing the mutton supply and assisting in the destruction of weeds on the fallows, they returned a considerable profit in the wool. Merinos were not so difficult to keep inside the fences as were the crossbreds, and the wool return from any rejected for export was greater in the case of the former. He had experimented with oats for green feeding with satisfactory results, and he advised putting this crop on stubble before seeding to produce early feed for fattening ewes and lambs. Sandy soil, fallowed in August last year, was sown with 1bush. of oats to the acre. This produced late spring green feed, and kept the fallow from drifting. The lambs could be tailed when between the ages of three days and two months, and he preferred the knife to the searing iron for this purpose, Stockholm tar being applied to the cuts. Foxes, which were causing trouble, should be poisoned during March, April, or May, a trail being used, the baits consisting of sheep's liver and strychnine. Mr. Upill said the best lambs were those that were first ready for the market; consequently he advised the crossbred. The knife was better than the searing iron for tailing. The latter was slower, and the wound did not heal so quickly or well. Mr. Butler preferred the crossbred lambs. It did not pay to hold them over for wool, and those fattened better than the Merinos. They should be tailed when between 14 and 21 days old. It was necessary to do this at the proper time, and he had found that lambs tailed with a knife were in some cases as much as 7lbs. better than those on which the searing iron had been used. Mr. Gleeson preferred the Merinos. Crossbreds were difficult to keep in the paddocks. There was always a sale for wethers, and it might pay better to keep these better than ewes. Mr. Neville liked the Shropshire and Border Leicester cross. Last year he turned the rams in with the ewes that had lambed too early for the feed and secured a second lambing, which sold at very satisfactory prices locally. In a season like the present it would pay to kill the lambs rather than run them on short feed, and put the rams with the ewes again. Good summer lambs were worth about 15s. in April or May. Oats sown on the stubble could be more profitably fed to great stock than to sheep.

Blyth July 18.

(Average annual rainfall, 16·46in.)

Present.—Messrs. A. L. McEwin (chair), A. P. and F. W. Kirchner, J. S. McEwin, S. R. Neville, F. Willshire, J. H., W., and J. Pratt, J. C. and A. H. Schulze, W. J. Ninnes, C. Lehmann, C. P. Schuster, A. Hamilton, T. Roberts, S. G. Shepherd, T., M., and J. Williams, E. C. Deland, H. Neumann, D. Crawford, H. D. Pedler, H. W. and W. O. Eime (Hon. Sec.), and three visitors.

Inspection of Mill.—At the invitation of Mr. Deland, members inspected his mill and were much impressed with the extent of the plant and the nature of the processes through which the grain passed before and during the operation of milling.

Annual Report.—The Hon. Secretary's report, which was presented at the meeting after the inspection, showed that eleven meetings had been held, papers being contributed at nine, with an average attendance of 21·4 members and 9·4 visitors. The year opened with 23 members on the roll and closed with 39. One homestead meeting had been held.

Pig-Raising.—A paper on "Pig-raising" was contributed by Mr. J. A. Pratt, as follows:—"With proper management pig-raising is a very profitable industry. In order to obtain the greatest success there must be regular and liberal feeding, with absolute cleanliness and kindness in handling the animals. The boar is a very important member of the herd, and should be a pure-bred animal of the best type obtainable. If the progeny are for market, get a boar that will produce the type of pig that brings the highest price. The introduction of a fresh strain will show more quickly in pigs than any other kind of live stock. If breeding stud pigs, careful mating is a most important point. The sow should be roomy, long, and deep, with broad loins and strong back; she will then have the capacity for carrying large litters. Like the boar, the sows should not be used for breeding until a good age. Sows breeding too young produce either small litters or large ones of uneven, weakly pigs. The young pigs should be weaned gradually, giving them small quantities of food when they are about a month old. This will relieve the sow and they will thrive better. If they are weaned suddenly they become stunted and do not afterwards grow as rapidly as they should. At two months their teeth are in a suitable condition to grind food. This, as a rule, is about the best period to wean them, unless they have been farrowed in the winter, when they will require to be longer with the sow. The Berkshire is the favorite breed in Australia, being well suited to the climate. In South Australia and some parts of Victoria the Berkshire and Essex cross is favored, and in other parts the Berkshire and Yorkshire cross is preferred. The Tamworth pig is noted for the great portion of lean bacon of the highest quality which it produces." Mr. McEwin, in discussing the paper, said that pigs paid best when eating waste stuff. It paid better to fatten stores than to breed. There was greater profit in January, February, and March than during the remaining nine months of the year. His pigs had not put on more than 20lbs. in weight since the frost set in. The Berkshire was the most profitable breed, and for breeding it was best to have small paddocks netted, with a straw stack in the centre.

Bacon-Curing.—Mr. McEwin would lay the meat flat on a table or flag shelf, sprinkle with salt and brown sugar and a little saltpetre. It should be turned two or three times a day for about two weeks. Mr. Schuster, to cure bacon, would mix a brine of 7lbs. salt, ½lb. saltpetre, and some brown sugar. Boil and let it cool over night, and then put the meat in a trough covered with the brine, and turn occasionally. Bacon must be in the brine for about two weeks and then be put into fresh water one day, and then hung in the smoke house. Mr. Pratt, to cure sides, would lay the bacon out, sprinkle with 2lbs. salt, a packet of spice, saltpetre, and brown sugar, and then would roll it and hang it up.

Nantawarra, July 17.

(Average annual rainfall, 15·90in.)

Present.—Messrs. T. Dixon (chair), S. Sleep, F. J. Sutton, A. F. Herbert, R. D. Nicholls, W. Smith, R. P. Uppill, G. L. Tucker (Hon. Sec.), and one visitor.

Laying Out and Working a Farm.—Mr. Sutton read a paper on this subject. Having touched upon the need for a thorough knowledge of his various soils, thorough cultivation, judicious manuring, and the selection of crops suited to the capabilities of the different paddocks, the writer said the homestead should be placed near to the main road, if possible, and be in a good position to work the farm. Due regard must also be paid to water supply. All buildings should be made substantially. The stables to stall at least 16 horses—assuming that the farm comprised about 1,000 acres—with a couple of loose boxes provided. The chaff and engine house he would include under the same roof as the stables, to minimise cost of timber and iron. The barn erected, a lean-to might be attached to either side. One for implements and the other provided with movable grating, for shearing during the season and general use at other times. Cow bails could also be put under this roof. Durable implements and machinery, simple as possible in construction, should be preferred, and these should be under cover when not in use. A few pounds spent in fitting up a blacksmith's shop would be repaid many times over in charges and time saved for repairs. Pigs and fowls with attention paid well. System should govern all the operations of the farm, and liberal dressings of superphosphate should be put in with the grain. To make a farm valuable it must be so worked as to produce good crops. The appearance must be orderly and tidy, and the management systematic throughout. Mr. R. D. Nicholls said that the house should be built west of the stables, which should be built open towards the east. In a lean-to, connected with the stables, harvesting machinery, etc., that was only required at certain periods should be kept out of the way. He favored building sheep-yards on a rise, as sheep were more easily driven up hill. The water-troughs should be on a limestone patch, not too near the stables. This would do away with mud and ensure a pure water supply. He also considered it essential that a few small paddocks should be set apart close to the homestead, in which to conduct experiments. Mr. R. P. Uppill considered that the writer of the paper advocated too extravagant a start. It was better to get to work on the land at first. This was the most necessary improvement, and the other things would gradually come in course of time. Mr. Smith advocated the making of wide gateways, as the time had arrived for quick working of the land, and consequently wider implements and machinery. Mr. Sleep agreed with the writer of the paper that the things he had mentioned were necessary, but thought it better to put the capital on the land, and to do other things by degrees. It was advisable to exercise caution in expenditure when making a start. Mr. Sutton, in reply, did not think it was advisable to keep harvesting machinery too near the stable. In regard to the water-troughs, he said a limestone rise was not always convenient, but a few loads of stone around the trough answered the purpose admirably.

Sparrows.—Mr. Sleep drew attention to the increasing number of sparrows, and considered that united action should be taken for their destruction. Members agreed with the speaker, and a general discussion took place as to the best methods of destroying the pests. As a recommendation from this Branch, the following resolution was passed:—"That the attention of all farmers is drawn to the necessity of each doing his share in the destruction of sparrows."

Northfield, July 1.

(Average annual rainfall, 19in.)

Present.—Messrs. Williams (chair), Dall, Kimber, Rowe, Goldney, E. W. Kelly, Wright, Roeger, and Mitchell (Hon. Sec.).

Seeding.—A short paper on this subject was read by Mr. Goldney. In order that a streaky drilling might not result, he said, it was necessary to level the seed in the box after filling. This would give an indication of how the seed was running, and if it were being distributed unevenly this could be remedied by the hand being thrust down into the pocket and the seed loosened. When the drill was becoming blocked by clay or moist earth, a good plan was to lower the pole and so raise the whole of the hoe. Where time was available, crossdrilling was a good idea, but, as a substitute, the broadcasting of a small amount of seed after the drill would be found beneficial. This applied specially to oats. Members generally agreed that crossdrilling took too much time to be practicable.

Riverton, May 22.

(Average annual rainfall, 20·48in.)

Present.—Messrs. F. Phillips (chair), Camac, J. W. Kelly, W. B. Davis, W. Legoe, W. Stacey, C. H. Castine, R. H. Cooper, E. A. Gray (Hon. Sec.), and one visitor.

The Pig Industry.—Mr. T. Camac, in a paper under this heading, said the pig industry, on account of the uncertaintly of the market, had been neglected. An oversea trade could be built up, as England imported £25,000,000 worth annually, and Australian bacon was realising from 60s. to 65s. per hundredweight there. He had found an acre of ground sown to barley annually was sufficient to keep about six breeding sows from May until the end of October, with the addition of a small ration of corn daily. Stone styes, 8ft. by 8ft., floored with flag, well ventilated and drained, were recommended. The Berkshire was a quick growing pig. Inbreeding should be avoided, and great care was necessary in feeding the breeding sows before and after farrowing.

Saddleworth, July 18.

PRESENT.—Messrs. Manning (chair), F. H. Kelly, Cornwell, Rex, Theo. Eckermann, Townsend, Scales, Snell, and Coleman (Hon. Sec.).

COST OF STRIPPING AND HARVESTING WHEAT.—Considerable discussion occurred on the question as to what might be taken as a fair average day's work with a stripper and a harvester, one man only with each. In stripping he must empty and "throw up" the heap; in harvesting he fills the bags, leaving them standing in heaps unsewn. Seven acres a day in a crop going 20bush. was finally decided as a fair average; this allows for a late start occassionally owing to damp or broken weather conditions in stripping. One acre more is allowed with harvester. The following estimates were submitted:—

ESTIMATED COST OF STRIPPING, WINNOWING, AND BAGGING A 20BUSH. CROP.

By Contract (Stripping at 22s. 6d. per day)—	£	*s.*	*d.*
Seven acres per day, 140bush. cost 22s. 6d., 250bush.	2	0	2
Winnowing 250bush. (77 bags at 195lbs.) at 6d. per bag	1	18	6
Wear and tear winnower, oil, &c., per day	0	2	6
Cost of stripping 250bush.	4	1	2
Cost 6s. 8d. per acre. 1bush. costs 4d.			
Actual Cost to Farmer.—			
Three horses' feed one day, 112lbs. chaff at £3 10s. per ton	0	3	6
" " 42lbs. hay at £3 per ton	0	1	2
Stripper, £50, wear, tear, and depreciation at 10 per cent. for 30 days, per day	0	3	4
Harness, wear, tear, &c., and oil per day	0	0	4
Team of horses, depreciation per day	0	1	0
Labor, one man stripping	0	8	6
Cost of stripping 140bush. only	0	17	10
Winnower and tools, wear and tear, &c.	0	2	6
Three men at 8s. 6d. per day, winnowing and sewing up bags	1	5	6
Cost of stripping 250bush. and cleaning only	£3	3	8
Cost 5s. per acre. 1bush. costs 3d.			

ESTIMATED COST OF HARVESTING AND BAGGING A 20BUSH. CROP

By Contract (Harvesting at 27s. 6d. per day).—	£	*s.*	*d.*
Eight acres per day, 160bush, cost 27s. 6d. 250bush	2	2	11
Sewing 75 bags (250bush.) at 1d. per bag	0	6	3
Cost of harvesting 250bush.	£2	9	2
3s. 11d. per acre. 1bush. costs 2¼d.			
Actual Cost to Farmer.—			
Four horses' feed, one day, 150lbs. chaff at £3 10s. per ton	0	4	8
" " 56lbs. hay at £3 per ton	0	1	6
Harvester, £85, wear, tear, depreciation (at 12½ per cent. for 30 days) per day	0	7	0
Harness, wear and tear, oil, &c., per day	0	0	6
Sewing 75 bags (250bush.) at 1d. per bag	0	6	3
Team of horses, depreciation per day	0	1	4
Labor, permanent farm employé, one man per day	0	8	6
Cost of harvesting—160bush cost	£1	9	9
250bush. cost	£2	6	6
3s. 9d. per acre. 1bush. costs 2¼d.			

Gain—Harvesting, £10 18s. 1d. per 100 acres.

Salisbury, July 1.

(Average annual rainfall, 18·57in.)

Present.—Messrs. Moss (chair), E. V. and A. J. Harvey, Tate, Frost, Bussenschutt, McGlashan, James, Neal, Judd, Bagster, Day, Fleet, Basford, Jenkins, and three visitors.

Question Box.—The meeting took the form of a question evening. Mr. Neal had successfully bred four foals from a mare with a bridle tooth. Messrs. Harvey and Bagster also supported the contention that mares with bridle teeth would breed. When trees bloomed and set out of season, the crop should be removed, as it was worthless; in any case it would badly affect the following season's crop. Oranges sometimes matured satisfactorily out of season. Members favored discriminate planting of stunted varieties of trees for shelter for stock. However, these would be found great robbers of the soil if planted extensively. There was a division of opinion as to whether it paid to grade seed wheat. Applications of Bordeaux mixture just before the bursting of the blooms were recommended for curl leaf disease.

Two Wells, July 15.

(Average annual rainfall, 16·36in.)

Present.—Messrs. A. Rowe, P. C. Cooper, H J. Wasley, R. Kenner, E. Green, L. Simpkin, J. Hanrahan, J. Rowe, and L. H. Dawkins (Hon. Sec.).

Breaking in Horses.—Members considered the best time to break in a horse was the latter end of the summer, when the beast was rising three years. It should be taught to lead and guide before being placed in harness. For the first few weeks it should be given little work. Kindness and firmness on the part of the person doing the handling were essential. The Hon. Secretary preferred handling the foal from its birth, but members thought this tended to make it crafty and cunning.

Watervale, July 14.

(Average annual rainfall, 27·17in.)

Present.—Messrs. E. E. Sobels (chair), W. Smith, G. Parker, C. Solly, A. Davis, O. Dunstan, F. Burgess, A. Burgess, D. Guthrie, O Ward, J. Scovell, F. Hunter, F. Hamp, J. Hamp (Hon. Sec.), and three visitors.

Farmers' Wool Clips.—The following paper was read by Mr. G. Parker:—"This question should interest every farmer, whether he has 50 sheep or 500, as the monetary gain which can be derived from the small amount of time spent at shearing cannot be overestimated, especially if it is done in a systematic way. Some say that with small lots of wool it does not pay to go to the time and trouble of classing; but having had practical experience in the classing of wool, I claim that the time is coming when it will be necessary for the farmer, whether big or small, to pay more attention to this part of the business. I do not think that there is a gardener in this district that does not strive to make the best possible sample of his currants or other fruit before placing them on the market. We find small lots of fruit as well and sometimes better graded than large lots. If it pays the fruitgrower to go to this trouble, will it not pay the farmer to the same extent? In the classing of small clips care should be taken that it is not overdone, as there is an agreement between the woolbuyers and brokers that any lines of less than four bales are to be treated as star lots, which are sold after the main catalogue has been dealt with, and which, therefore, do not command the same competition as a lot of four bales or more. The average farmer's flock very often contains a certain percentage of crossbred sheep, more especially lambs, as the majority of farmers breed export lambs. These fleeces should be very carefully watched and placed in a bale by themselves, as they very often lower the selling price of the whole clip if allowed to remain with the Merino fleeces. Care should also be taken that the shed is perfectly free from vegetable matter, such as chaff, straw, &c., as the introduction of this into wool has a very detrimental effect. After the sheep has been shorn it is necessary to throw the fleece upon a table without unnecessarily breaking it. Skirting depends largely upon the size of the clip to be handled. With a small lot it is not necessary to skirt heavily, but if the clip is from 300 sheep or more it is very advisable to skirt all the vegetable matter off the fleece. Start skirting from the back of the front leg, and work towards the head. After having treated the front portion of the fleece, give attention to the hinder portion, and skirt from the back of the arm to the point of the tail. The amount of skirting varies with the amount of inferior wool which is upon each fleece. After skirting the hind portion of the fleece, bring that back to about the middle of the fleece, and throw both edges into the centre of the table and roll the fleece. As a rule the shoulder will be on the outside. This generally has a more attractive appearance than any other portion. After this, all that is necessary with small clips is the baling and taking out the discolored and inferior fleeces. Wool that is carefully pressed generally has a more attractive appearance when opened for the inspection of buyers. The skirtings from a small clip of under 300 could be baled n one lot, with the exception of the urine-stained purses from the crutches of the ewes and bellies of the wethers. This wool will not scour clean and will consequently not take dye so well. With a clip of, say, from 300 or more, it is possible to skirt more heavily and class the wool into two or three different lots, and also to re-skirt the pieces and make two lots of them. After the fleeces have been skirted, place them in a bin until there are sufficient for baling. Put all the lightest and brightest fleeces together and brand them 'AA.' The heavier and stronger, brand 'A,' and the very fatty and discolored ones, brand 'B.' Skirt the pieces and brand the best 'A Pieces,' and the rest 'Pieces' The bellies must also go by themselves. If any crossbred wool has been shorn, it could be rolled and placed in a bale or bag by itself. The locks and floorings can all be swept together and put into one lot. After the wool has been dealt with in this manner it is in a form attractive to buyers. Placing the wool into different classes enables them to form a better idea of the yield of scoured wool in the clip, and as a result the line is more sought after. In conclusion, I should like to draw attention to the South Australian School of Mines in connection with wool-classing, as the work done by the expert and students of that institution has been the means of bringing thousands of pounds into the pockets of the agriculturist and sheepfarmer in South Australia." The majority of members agreed with the views expressed by the writer of the paper, and thought it advisable for farmers to pay attention to the classing of their wool, whether they had large or small flocks.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Pine Forest, June 17.

(Average annual rainfall, 14·15in.)

PRESENT.—Messrs. D. Carman (chair), A. Hewett, H. Adams, S. Barr, W. Attenborough, R. D. Goodridge (Hon. Sec.), and one visitor.

MARKETING WOOL.—Mr. Carman read a paper on this subject. Whilst the Wool Instructor had urged that farmers were losing 1d. per pound on their wool through careless marketing, he said, the wool brokers stated that it would not pay to be too particular in this direction. He suggested that the brokers might handle farmers' clips in the way they dealt with the skins, *i.e.*, classifying them and selling according to value. Mr. Hewett thought the brokers should not be called on to do this, the farmers should class their wool themselves. Co-operative classing and marketing should be an advantage. If small clips were marketed together as one line, a better price would probably be secured. Mr. Attenborough did not consider Mr. Hewett's suggestion practicable, some farmers might consider their wool better than that of others; consequently, there would be dissatisfaction. Little benefit was derived from classing small clips.

WESTERN DISTRICT.

Coorabie, June 14.

(Average annual rainfall, 11in. to 12in.)

PRESENT.—Messrs. C. T. Giles (chair), W. H. Wheadon, D. Riddle, C. B. Atkins, V. S. Kinsley, N. M. Roberts, C. Hobbs, E. Attick, R. Weston, F. Underwood, J. Murray, W. Cousins, C. A. Fox, H. Coppins, E. Oats, E. Stretton, B. Giles, W. Grivell, G. Menzel, G. Riddle, F. Gurney, T. Gurney, G. Cabot, H V. Hobbs (Hon. Sec.), and five visitors

PIG-KEEPING.—Mr. V. S. Kinsley read the following paper :—" It is a surprising fact that in a district like the West Coast, where we practically rely upon our wheat crops as the money maker, more serious attention is not given to pigs. Most farmers are in a position to keep a cow or two, and so with a fairly constant yield of milk over and above that which they can themselves use, here lies the foundation for profitable pig-raising. We all know that it does not pay to rear calves, but it does pay to keep pigs, and very handsomely, too, if the farmer will treat the question as a serious business matter. The Irish farmer regards his pig as the ' rent payer,' and we might reasonably do the same From the Australian newspapers it is plain that there are huge possibilities for South Australia as a pork and bacon producer. We must produce good flesh, and that must be done quickly. A pig will eat practically all kinds of food, and if this is judiciously prepared it will rapidly convert young pigs into animals of marketable size. Situated as we are, we have no chance of supplying the freshly-killed carcass to a bacon-curing factory or to a freezing works for export, therefore we must study carefully the subject of curing the hams and bacon, and there is no reason whatever why a farmer should not do it as well as any wholesale factory. Great care must be taken in cutting the animal intended for curing into the required shapes. Cutting anyhow, as though we were cutting up a ration sheep, will not do. It must be cut to a certain pattern or style to suit the merchant, and later on the retail grocer. In preparing pork for bacon and ham, let the pig hang at least 12 hours before cutting, that is if the weather is suitable. Do not try curing in very hot weather, though this can be done as in colder seasons, but much more care must be taken throughout the proceedings. The pig must be well bled, and in warm weather all the bones should be taken out For salting use a shallow packing case. If it is the intention of the farmer to go in for this work thoroughly I recommend a specially made trough, say, about a foot deep and 3ft. long by 18in. to 2ft. wide. However, in any case the main point is to retain the brine or liquid about the flesh until the period of salting or curing is complete. For a pig of about 150lbs., use about 10lbs. of salt, about a small cupful of saltpetre, and about two large cups of sugar, *i.e.*, something like a pint in measure. To this some curers fancy the addition of a little spice or ground ginger. We may safely add about 2ozs of mixed spices The whole of the salt and other ingredients should be well mixed together, and then some should be sprinkled in the trough bottom. The sides of the pig should be placed in skin downwards and a plentiful supply of salt mixture rubbed in. On top of this place the hams. After about a week turn the sides and hams face downwards, rub well, and repeat this process in a fortnight. In three weeks the bacon and hams should be ready to take out. After this wash off all surplus salt and hang them up to drip. In about a couple of days do any rolling or smoking that is intended. In the case of rolling sprinkle the flesh with flour and dry thoroughly with a cloth. Then use skewers on a board and roll up towards the shanks with the best cord obtainable. It should then be bagged and hung in a draught for at least a month, when it is fit for use. For smoking use a large packing case ; suspend the hams and bacon from the lid or top, and cover it with a few bags to keep in the smoke. The fire should be about 5ft or 6ft. away from the case, with a trench cut about 6in. by 6in. running under the case to convey the smoke. Use wood that does not burn too fiercely. Sawdust or cocky chaff is good, in fact, anything that smoulders rather than flames, and so creates a good smoke. The bacon should be left in the smoker until it attains a nice brown color. A little practical experience will soon teach the depth of color that is required according to taste. For market purposes a light-golden brown is best. Never place the smoking fire directly under the smoking case As to the best type of pig to keep, I most strongly recommend the Essex. It is easily produced, being a cross between the Black Berkshire and the Red Tamworth. The former carries a great amount of fat and the Tamworth is principally lean ; so the result gives ' streaky bacon.' This breed is admirably adapted to a warm climate and does very well in Australia. The young pigs up to, say, 10 weeks old are somewhat disappointing in their growth, but after that date it takes a very good judge to guess their weight. They generally weigh much more than their appearance suggests. The pigs should always be well housed and attended to regularly. They thrive much better when kept under clean conditions and in styes that are draught proof, particularly when very young. The youngsters should always be encouraged to feed; they soon learn to eat. I recommend placing a low, shallow trough in such a position that only the suckers can get to it. Start feeding from this with stale bread crusts and other such odds and ends with skimmed or separated milk. The addition of a little treacle and hot water is a great inducement for the little ones to look out for their own living. This is a great saving on the sow. Molasses is a good addition to the general feed for pigs of all ages. The trough should never contain more feed than will be cleaned up each time. Always endeavor to keep increasing the daily rations. I strongly recommend barley in preference to wheat as a general feed. If it is intended to take up pig-keeping as a serious business proposition add maize and a small proportion of linseed. Always remember that separated or skimmed milk is far preferable to water. It contains a certain amount of nourishment. Sows in their third and fourth litters are the best from which to breed, particularly for the maintenance of the standard of the stock and breed. The litters are always larger, and so are the youngsters; they do better, and the sow does not lose so much of her condition. I do not favor the practice of using young boars." Mr. E. Oats favored the Berkshire breed of pigs, and expressed the opinion that the Tamworth was difficult to fatten. He agreed with feeding milk of any sort to pigs whenever possible, and considered wheat heads a good and economical food. Any dry grain should be scattered about in the loose earth. The pigs seemed to enjoy "nosing" about for it and chewed the grain better; therefore getting more sustenance out of it. The Chairman said pigs throve better on three small feeds per day than two larger ones. Mr. Atkins favored the Berkshire breed. He advised the use of brown sugar with the pickle Other members had used molasses instead of sugar with satisfactory results.

Coorabie, July 12.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. C. T. Giles (chair), E. J. Stretton, D. Riddle, J. H. Murray, N. M. Roberts, W. H. Wheadon, C. B. Atkins, V. S. Kinsley, V. R. Weston, F. Woodforde, E. J. Oats, C. A. Fox, C. Hobbs, W. G. Wheadon G. Menzel, F. Gurney, A. Broadfoot, T. Gurney, B. Giles, A. Riddle, W. Grivell, G. Riddle, H. V. Hobbs (Hon. Sec.), and six visitors.

Producing and Marketing Wheat.—In a paper under the heading "The Cost of Producing and Delivering Wheat to Market," Mr. V. S. Kinsley said—"In preparing an estimate of this description one thing must be borne in mind, and that is that all farmers do not think or act alike, so that there may be a great diversity of opinion, and still more so as the land included in the area represented by this particular Branch of the Bureau at the Far West end of cultivated South Australia presents so many changes in its character. For instance, we have the hard, red flats, and the lightest soils—almost pure sand in some instances—of the mallee country; consequently the cost in seed and super., and of tilling the soil into a good seedbed will vary as much as 100 per cent. to 200 per cent. in the different classes of land. My contention at the outset is that statistics on this subject can only be taken as a guide to enable each individual farmer to arrive at his own particular cost. I shall purposely refrain from comment as to how any class of land should be prepared for a seedbed, only touching upon such points as are necessary to arrive at an average cost. I am presuming that all the horses will obtain their own feed during the off working seasons, *i.e.* on the stubbles, self-sown and permanent grass lands. So that it would be unfair to charge up against the cost of wheat production the keep of horses during such period. By taking the rent and taxes of the whole block into consideration, this charge will cover their grazing cost, coupled with their manurial value in the stable yard and paddocks. Again, there arises the cost of fencing and wire netting, and against this I propose to grant a 20 years' life to a well set up rabbit-proof fence; consequently this will add a 5 per cent. debit to the cost of each season on the cultivated area. I will presume that we have a block of, say, 1,000 acres, although its size matters nothing, most of which is cleared, and 400 acres will be in crop and 200 acres under fallow, the balance being made up from rough country, scrub, and home grazing paddocks. I allow cost of hay feed for the horses during the working season, chaffed or otherwise, and I make no difference in cost whether it is chaffed or not. If we have a chaffcutter and engine or horseworks, I consider that the interest, labor, and depreciation in plant is compensated for by the loss that occurs by waste in feeding long hay as against cut. I allow nothing for the residual value of a crop of wheat for feed purposes, *i.e.*, cocky chaff or collected straw, because, in my opinion, after we take into consideration the cost in labor of saving and using, combined with wheat and other ingredients necessary to obtain value as hard horse feed, these cost considerably more than hay to the farmer; therefore I am charging up the cost of hay as the cheapest feed. In arriving at such cost I take it that its value can only be that which would ultimately be calculated from the average wheat yield per acre. So that if the total crop averages 10bush. and sold at 3s. per bushel, the hay would be worth that amount to us and no more, which means 30s. per acre. It is only fair to take the cost of machines, &c., at their new value. I charge no interest upon them at all, but depreciation on a 10 years' life, which means 10 per cent. per annum. Some of the implements will last a careful farmer much longer than this, and some may not last so long. I think, therefore, this charge will be sufficient. I have carefully read and studied a paper on the same subject that has been written for another Branch of the Bureau, and appearing in the last April number of the *Journal of Agriculture*, page 1050, and I do not agree with several of the charges that are made there. Particularly I cannot allow any interest charge on general capital to be made against the cost of production, for in my opinion the interest charges will be contained in the profit derived from selling or even using the produced wheat. In support of this opinion I state that if a person invests in a bank or industrial company, the interest or dividend that he receives for the unsecured loan of his money is solely upon the profits of that trading concern, and only then, after full allowance has been made for depreciation. One man can fallow and seed the 400 acres with eight horses in about 10 weeks, and harvesting will take about the same period, damp or wet weather included, with the assistance of a boy to sew bags and bring a change of horses for harvester. I allow ¾bush. seed and about 55lbs. super. per acre, eight horses averaging £25 per head, plough £50, cultivator £25, drill £50, harvester £100, and dray £20. Delivery of wheat to port from Coorabie is worth 6d. per bag, sacks being worth another 6d., although they actuallly cost a little more, but as the sack is weighed in and paid for at the wheat price, this reduces its actual cost slightly. The wages of one man for fallowing 200 acres and afterwards ploughing, together with the other operations at seeding time—completing the 400 acres for crop—will absorb 14 weeks at the rate of 30s. per week plus cost of board and lodging at 12s. per week, equalling £29 8s. Harvest wages at same rate, with the addition of a boy, whose wages and keep would be 22s. per week extra, will equal £32 for the 10 weeks. I do not allow any charge for depreciation on horses against the cost of wheat production, for in the hands of a shrewd farmer he will have at least 50 per cent. of mares in the team; therefore the annual value of foals will cover the loss on capital on this item. The cost of hay at 30s. per acre from 35 acres will mean £52 10s., which amount should be sufficient to see the team through the working seasons. Depreciation is to be allowed upon about six miles of rabbit-proof fence surrounding the crop and in subdivision, costing about £200 in capital outlay, and 5 per cent. will be adequate. There is another cost to be averaged, and that is for scrub land that has to be cleared. If half the area be allowed under this head at 15s. per acre, and a 5 per cent. charge made against it, this will be somewhere near the mark. The whole of the costs enumerated will work upon such average figuring at £326 1s. 10d., which means 16s. 3½d. per acre. The profit on a 10bush. average at 3s. per bushel at the Port will be 13s. 8½d. per acre, or £276 3s. 4d., including wages and keep for the working period, on one average crop of wheat. Summary.—Fence depreciation, £10; implements depreciation, £24 10s.; rent and taxes, £4 3s. 4d.; seed, £45; super., £50; sacks, £33 6s. 6d.; cartage, £33 6s. 6d.; twine, 12s. 6d.; wages, £61 8s.; hay, £52 10s.; scrub interest, £11 5s.; a total of £326 1s. 10d." Mr. Riddle thought the amount of hay allowed for horsefeed insufficient. The Hon. Secretary thought depreciation in the value of horses should be taken into account. The rearing of foals was a separate line, and not a necessity in the production of a wheat crop. He considered £3 per head per annum a fair amount for depreciation.

Goode, June 19.

(Average annual rainfall, 12in. to 13in.)

Present.—Messrs. D. J. Tonkin (chair), J. G. Nicholls, N. Packer, L. B. Hughes, A. B. Gue, S. O. McPherson, W. Burner (Hon. Sec.), and two visitors.

Rabbit Destruction.—This subject was discussed at length. The Hon. Secretary said that successful results had attended the following method tried at Denial Bay:—A jam tin, half filled with water, into which was placed a small piece of phosphorus, a little bisulphide of carbon, and then a little rock carbide was quickly thrust into a burrow, which was immediately closed. Following the evaporation of the water, the phosphorus fired in the burrow. Mr. Hughes had secured good results from the use of raspberry jam and strychnine. The Hon. Secretary drew attention to the possibility of the loss of stock through their eating the bones of rabbits destroyed in this way.

Mangalo, June 21.

(Average annual rainfall, 14in. to 15in)

Present—Messrs J C. Busch (chair), W. E. Waters, C. H. Klingberg, J. W. Deer, H. H. Klingberg, J Meiglich, A. Schiller, H. Mackley, jun, J H. Cleave (Hon. Sec.).

Mallee-Farming.—Mr. W E. Waters contributed a paper on this subject, in which he stated that farmers should work systematically. It was essential in new country to secure a good stack of hay and a good supply of water. All rubbish should be cleared off the land before ploughing was commenced. Stubble should be burnt in the hot weather, as many of the mallee shoots would then be killed. New land should be ploughed as early as possible to enable the sun and rain to sweeten it. Stubble and grass land should be ploughed after rain, as there was then more chance of the weeds being killed Cropping should be completed by the end of June to allow time for the preparation of the soil for the following season Mallee shoots should be cut at the first opportunity. As much of the fallowing as possible should be done immediately after seeding, in order to get the benefit of the winter's rain. One acre of well-worked fallow land was worth three acres of land not so treated. Members generally approved of the ideas expressed by the writer of the paper, and agreed that it was necessary to cut mallee shoots early.

Miltalie, June 14.

(Average annual rainfall, 14·55in.)

Present.—Messrs. P. G. Wilson (chair), J. R., J. W., and E. Story, J. R. Hill, S. R. Searle, W. G. Smith, J. S. Jacobs, C. and A. Degner, A. M. and T. A. Wilson (Hon. Sec.), and four visitors.

Fallowing.—Mr. Hill read a paper in which he stated that farmers were slow to recognise the value of well-worked early fallow. Some even did not commence ploughing until the spring, and kept on till the hay harvest. Weeds were allowed to grow, and an attempt was made to feed these off with sheep, cattle, or horses, the plough again turning the land right back at seeding time. The drill followed close behind this, and the crop was left to take its chance, which was a very poor one. The plan he recommended was to commence fallowing the day following the completion of seeding, ploughing the ground well with a good plough, and turning the weeds well under. The fallowing should be completed by the end of August, and should be harrowed once crossways to secure a good tilth. During the latter part of September the scarifier should be put in. If mallee shoots were troublesome a disc implement should be used, and the scarifier harrows previous to harvest time. Sheep could be run on the land until March, and it should then be again cultivated to secure the full benefit of the early rain. The scarifier harrows should after this be kept going until seeding time. Members generally agreed with the ideas of the writer of the paper. Fallowing should be commenced early, although frequently the soil was found to be too hard. The Chairman suggested that if the land to be fallowed were scarified or disked in February, it could be worked early in June or July.

Miltalie, July 18.

(Average annual rainfall, 14·55in.)

Present.—Messrs. T. A. Wilson (chair), I. R. Hill, H. Brine, I. W. and J. P. Story, M. H. Wilson, E. Story (Hon. Sec.), and four visitors.

The Social Side of a Farmer's Life.—In a paper on this subject Mr. J. W. Story urged that is was a mistake even for the older farmers to entirely cut themselves off from sport, while to keep young people at work from daylight to dark, six days a week, would dwarf the intellect and generate an uncongenial spirit. While recognising that during such times as seeding and harvest pleasure had to give way to long hours of work, the rural men, as a class, would do well to cultivate the social side of life. It was wise to take an occasional half-day off. A Bureau social evening occasionally would be of value. Visitation among farmers should be extended, for, apart from the social element, one could always learn something from his fellow farmer. In the discussion, Mr. Wilson thought sport was an essential element in young life, provided that one worked hard during working hours. The Chairman emphasized the need for farmers to extend their reading, while Mr. Hill thought such sport as Bureau conferences, homestead meetings, field trials, &c., were more in the farmers' line than football and similar pastimes.

Penong, July 12.

(Average annual rainfall, 11·93in.)

PRESENT.—Messrs. W. Saunders (chair), A. Shipard, W. B. Prider, and J. Oats (Hon. Sec.).

CONSERVATION OF FODDER.—Mr. A. Shipard read a paper, in which he urged the wisdom of making better provision in times of plenty to supply a sufficiency of stock feed in bad seasons. Even inferior cocky chaff and good straw should be put by, though the expenditure of a few pounds was sometimes involved in the work. A few sheets of galvanized iron would preserve such reserve supplies for a number of years, and one never knew when it would become very valuable indeed. Mr. Farrelly agreed that a great deal of feed was wasted every year in this district. Bran and cocky chaff made very good stock feed, and every farmer should have a stack of straw. The Hon. Secretary and the Chairman pointed out that the heavy rains in February last damaged so much wheat chaff that it was useless to attempt to preserve it.

Roberts and Verran, July 16.

PRESENT.—Messrs. R. Johnson (chair), A. T. Cowley, F. Masters, E. Phillips, H. Ede, H Sharman, J. H. Buttfield, F. Imhoff, W. Sharman (Hon. Sec.), and eight visitors.

FALLOWING.—In a paper on this subject, Mr. A. T. Cowley said there was little to be gained by fallowing land in this district the first year after clearing. The scrub fire would tend to sweeten and enrich it to a certain depth ; it should be worked to this depth, and then drilled. This practice also saved considerable expense that was involved in clearing when fallowing was carried out. This could be best commenced after two or three successive crops had been taken off. Continuing, the paper read—"The object is to produce, or at least to prepare, sufficient nourishment in the soil to feed and sustain a profitable crop, and to keep that nutriment in the soil until the crop is ready to make use of it. We may as well take into consideration at the outset the fact that it is impossible to grow a blade of wheat from earth alone, however rich that earth may be in 'food' qualities. In fact, earth is not plant food until converted into it through the agency of other 'elements.' Only a very small percentage of the soil laid open to treatment can be thus converted in any one year. The greater that percentage, the 'richer' the land. We have to deal, then, not only with the soil itself, but with the action upon it of light, heat, cold, rain, dew, frost, gases, chemicals, and air. The man who knows best how to work his land to obtain certain results is the man who knows most about the way in which these elements work in the soil and the conditions under which they work best. There is a time to plough, and I believe the best time is early—commencing in June or as soon after as possible. There is a correct depth to which to plough and which varies according to the quality and general condition of the soil, and also, in some degree, according to whether we desire to pull out stumps or leave them in the ground. When ploughing deep, plough the land early and afterwards work lightly as many times as possible between fallowing and seeding to give time and opportunity for the action of air and moisture upon the soil disturbed. The best condition in which to plough or work the soil is when it is charged with moisture—to what degree depends upon the nature of the land. Some ground in this locality never gets too wet to work, other ground may. Some never gets too hard to work when dry, but in my opinion the preparation of plant food is not promoted to the same degree in dry working as in wet, and there is, I believe, something more than an imaginary risk of encouraging takeall germs in a loose-natured soil by dry ploughing. The conservation of moisture, in this district, is quite as important a consideration as the production of plant food. Food without water is as useless to a plant as it is to man or beast, and we must be as much in earnest about getting the rain into the soil when it falls, and keeping it there, as we are about getting it into our tanks and holding it for future use. The best way to get it in is to have the soil open, loose, and free to receive it. Keeping it in depends upon the top and bottom conditions of the soil. Where the subsoil is clay it may safely be encouraged to go down as deeply as possible. It cannot escape below so is safer away from the surface. Where a limestone or other class of rubble subsoil forms a natural deep drainage system the working should be of a nature calculated to keep the moisture near the surface, and it is in such a case that what is as nearly as possible a non-evaporative surface should be maintained. A solid bottom must be left unbroken between the ploughing and the rubble below; this, provided the soil may be loosened as deeply as thought desirable, to absorb, if possible, all the moisture that comes upon it. Succeeding workings should deal with the surface only, and should occur, if possible, whenever a sufficient quantity of rain falls to give the surface any inclination to 'set' or become firm; the object being to keep the surface so open and loose that the moisture receives no encouragement to permeate the extreme top 'layer' of soil. Thus it is shaded by this light layer from the sun's rays and sheltered from the wind—the two great evaporating agencies—and the loss is reduced to a minimum. At the same time the surface of the soil itself is open to the beneficial effects of sun and air. Fallowing, I believe, is directly and indirectly the most effective method of destroying undesirable plants such as mallee shoots, shrubs, and noxious weeds. Every working of the land destroys young plants and encourages the germination of remaining seeds to meet a similar fate later on. Any shrubs that have not been torn up in the first ploughing receive considerable damage, and few will survive by the time the crop is sown. A few shoots are torn off the stumps each time, and the stumps themselves are bruised and shaken, which soon begins to tell on their health, especially if the fallow has in the first place been ploughed deeply enough to tear up the strong feeding roots running 4in. or 5in. below the surface of the soil. After being subjected to rough treatment on several occasions during the eight or nine months of fallow working there will be considerably fewer shoots for the 'slasher' to deal with after the crop is drilled in, and if, just when a fresh growth, young and tender, is making yet another struggle for existence, a good stubble fire is obtained (which should follow as one of the benefits of fallowing) there will be probably not more than two or three stumps to the acre left alive to produce another crop of 'shoots.' I cannot claim to have proved this yet by experience on fallow, but I have 35 acres on which in two years from the time it was cleared the stumps were practically all killed with plough and fire. On my first fallow here, this year, I have seen the thinning out process, and am satisfied that if a stubble fire is obtained after harvest there will be few, if any, shoots to grow again. I fully believe that the threefold purpose outlined here can be served by fallowing, and that the productiveness of this country will be demonstrated, and that to our profit, when we have established a thorough system of fallowing." Mr. E. Phillips would use a small plough for fallowing, and so pull out stumps; he favored deep ploughing. Mr. Masters thought ploughing to a depth of from 2½in. to 3in. sufficient for this district. The Hon. Secretary thought the disc plough more satisfactory than the share for destroying shoots. The majority of members favored early fallowing to a depth of about 3in.

Utera Plains, June 21.

(Average annual rainfall, 12·06in.)

PRESENT.—Messrs. Sinclair (chair), J. and M. Abrook, H., T., and G. Hornhardt, Venning, Hier, Gale, Stephens, Lee, H. and G. Barber, Warnes, Guidera, A. Ramsey, (Hon. Sec.), and 50 visitors.

POULTRY.—Mr. W. Hier read a paper in which he said that, generally speaking, there was room for improvement in the methods of keeping poultry adopted in this district. The quality of the birds, and not their numbers, should be the chief consideration. They would do best on farms possessing low scrub in which they could find shelter. A good style of nest, which would not be easily found by crows, was made by digging small holes in the ground, and over these placing "dugouts," leaving just sufficient room for the hens to pass in or out. Care should be taken to place them out of danger of flooding. The erection of scarecrows was also frequently effective. Turkeys could be kept with advantage on some farms, but plenty of room was necessary. A turkey hen was a first-class mother for young chickens, but she should be confined in a fairly large yard. A flock of these birds could be built up by securing three or four young hens and a two-year-old cock, unrelated to the hens. Another gobbler should be secured after two years if it was desired to breed from the stock bred on the farm. Ducks and geese would do well on farms through which there were running streams, but otherwise they would not pay. The same care should be taken with breeding as with turkeys. The best time for extensive breeding in this district was July and August, but chicks could be reared all the year round where sufficient shelter was available. Old hens should be fattened for the table. Generally they should be killed off after the second season. When feeding turkeys or hens, the grain should be scattered on soft earth. Wheat for ducks should be put into water or in small heaps on the ground. Constant activity was essential to the health of all poultry. Ashes and lime should always be available. Laying ducks should be yarded at night.

Yabmana, July 12.

(Average annual rainfall, 15·14in)

PRESENT.—Messrs. M. K. Frost (chair), F. A. and H. Beinke, J. F. and A. Robertson, J. G. Pengelley, W. Schirmier, G. W. Story, J. N. and A. D. McCallum, H. P. McCallum (Hon. Sec.), and three visitors.

SHEEP ON THE FARM.—Mr. J. G. Pengelley, in a paper on this subject, advised farmers to go in for sheep, even if only a few were kept. They would be found very effective in keeping down weeds on the fallow, but they should not be put on this until cattle and horses had been run on it. Although they might not be fattening, the value of their wool was increasing. Old sheep should not be purchased, as they seldom did well, and the wool was short and sticky. For the farmer who went in for breeding on a small scale, the crossbred would be found more profitable than the Merino, the Lincoln-Merino cross mated with a Shropshire ram being most suitable for this district. The lambs were larger, and matured earlier than those of the Merino. The mothers were quieter, and generally suffered less on account of the shortage of feed in the event of a late season. These advantages more than counterbalanced the greater wool value of the Merino. Mr. J. N. McMcCallum preferred the Merino, on account of the difficulty with the crossbreds getting through the fences; the wool also was better. Mr. F. A. Bienke's flock of crossbreds last year cut an average fleece of 10lbs. These were best in a district such as this where meat was difficult to procure. Messrs. G. W. Story and J. F. Robertson preferred the Merino, as the skin and wool were more valuable. As a butcher's sheep, however, the crossbred was best. Whilst there was a possibility of the mutton market being over supplied, the Chairman said there was very little likelihood of the wool market becoming glutted. Members generally favored the Lincoln-Merino as the best cross.

Yallunda, June 21.

(Average annual rainfall, 18in. to 19in.)

PRESENT—Messrs. H. P. Cabot (chair), W P. Cabot, J. S. Perry, A. Cabot, G. A. Teakle, A. V. Teakle, A. G. Price (Hon. Sec.), and four visitors.

FALLOWING.—In a paper on this subject, the Hon. Secretary stated that the absence of fallow land in this district in the past was due to an insufficient area of cleared land, and the necessity for giving time to such work as fencing and clearing. Well-worked fallow enabled the farmer to make an earlier and better start at seed time, and the productiveness of the soil was increased. The best system of working was to have the land under fallow one year, under crop the second, and under grass the third year. Where the holdings were not large enough to allow of this, it was necessary to fallow the stubble. The soils in this district, if well worked, should produce a payable crop every second year, as there was a heavy rainfall and it was practically new land He would commence fallowing about the 1st of August. The share plough was preferable to a disc implement. It was advisable to work as much as possible with the plough, turning the furrow down hill Generally, the soil should be turned to a depth of 4in. or 5in., and the ploughing should be completed by the end of September. Numerous weeds would probably appear in October, which would necessitate reworking with a lighter implement Except where there was rubbish, such as roots, on the land, a cultivator of 15 or 17 tines, cutting a width of 7ft. or 8ft., would be found light work for the plough team, but where the weeds had made strong growth the skim plough would be most serviceable It was advisable to cultivate to the full depth of ploughing, as the soil was liable to set down hard. After the rains in February and March, he would work the ground to a depth of 4in. At seed time a light spring-tooth or similar implement which could be worked with four or five horses could be put over the fallow, and the drill could follow this. He did not favor harrowing, except in cases where land had been lying out for a number of years, when it would usually break up roughly in the ploughing. With an average season he advised sowing wheat on the fallow. Too early sowing, however, involved the risk of the seed malting. The balance of the land could be sown to oats or barley. For the past three years he had secured good results of hay from stubble land, ploughed with the February or March rains and sown to oats at the end of April. It would not be long before fallow paddocks were as much in evidence in the new as in the older districts. Members generally agreed with the ideas expressed by the writer of the paper.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Berri, July 12.

Present —Messrs. W. F. Clayer (chair), A. P. Wishart, F. Arndt, J. McGilton, W. Powell, A. Stahling, S. Phillips, V. Fowler, W. Fiedler, R. Koska, R. W. McCreanor, C. H. Virgo, W. Napier, S. Guernsay, T. L. Hughes, M. Mahoney, C. Harris, E. G. Mitton, E. Day, and W. R. Lewis (Hon. Sec.).

Experimental Horticulture on Murray River Reclaimed Areas.—The following paper was read by Mr. F. Arndt: —"Now that the South Australian Government has embarked upon an extensive scheme of irrigation works, with Berri and Waikerie partly completed, and with such large areas as Cobdogla and Ral Ral soon to be started, the question naturally arises to what uses are these lands to be put. So far, the only product of the irrigation areas along the Upper Murray valley has been fruit, which has been disposed of either in the fresh or dried state. It is, however, the dried fruits industry that has been the making of the Murray irrigation settlements, as the export of fresh fruit to other districts of the Commonwealth has been but small in comparison. But profitable as the dried fruits industry has undoubtedly been, both leading growers and merchants have issued a solemn warning that certain lines have reached the limits of Australian consumption, and that others will soon follow. This is the case with currants and raisins, and there is no hope of successfully competing with the Mediterranean product in the markets of Europe. The Sultana also is in danger of being overdone, for although the higher grades found a ready market in the older countries, to successfully compete with the output from the Levant it would be necessary for the Australian grower to be satisfied with a much lower price for his article than he has secured hitherto. Dried apricots have for some time been produced in sufficient quantity to supply the local demand, but there is said to be a demand arising for them in England. There seems to be an increasing local demand for dried peaches, but owing to Californian competition there does not appear much hope for the Australian grower to dispose of this product profitably on the London market. This, then, being the position of the dried fruits industry in Australia to-day, it is obvious that if the bulk of the area which the Government intends to bring under irrigation, whereby the irrigable area of South Australia will be trebled, is given over to the production of dried fruits, there will be such an over-production that the whole industry will be seriously disorganised, if not ruined. Therefore it is absolutely necessary that the greater portion of the new irrigation areas should be set aside for the production of other horticultural or agricultural produce than that already being produced. For this reason it is clearly the duty of the Government to insure the financial success of their irrigation enterprises—that the lands are planted with crops that yield a living to their occupiers. What new lines of agricultural produce may be profitably grown has not yet been determined. A lot of experimental work will be necessary before the success of any new line of agricultural activity has been fully demonstrated, and here is surely a splendid opportunity for the Government. It was no doubt for some such reasons as these that the Government three years ago set aside 70 acres of the best irrigable land at Berri; but far from being an experimental station wherein the suitability of new types of trees and plants to the district was being demonstrated, the experimental farm has only been one such in name. The greater portion of the farm has now been planted with oranges, vines, peaches, apricots, and lucerne, varieties of plants that experience has long ago proved can be successfllv grown along the river, the only thing pertaining of the nature of an experiment being a patch of a few hundred Smyrna figs. In fact, the farm has been laid out on the same principles as a commercial orchard, and when its many acres of fruit trees and vines come into bearing, will become a competitor with the settlers in the markets of the State A statement was made some time ago by one of the officials of the farm that the farm was not so much concerned with the testing of new varieties of plants to the conditions of the district as with manurial and irrigation tests. Surely this was but an excuse to disarm criticism, for have not the experience of Renmark, Lyrup, and other river settlements long ago successfully solved these problems? It is not to be denied that all the trees and vines planted in the farm are looking exceedingly well, and that new settlers without local experience may learn a great deal about the culture of trees known to succeed in the district; but a walk through an up-to-date orchard at Renmark or Lyrup would prove equally instructive. If a small area of land, say 10 acres, had been set aside and planted with trees of proved varieties as an object lesson to new settlers, the remainder of the farm being given over to horticultural and agricultural experiments, the ideal would no doubt have been reached, and the farm would then have been in fact as well as in name an experimental farm. After due consideration I have come to the conclusion that there are certain varieties of trees and plants which would perhaps prove suitable for growth under conditions existing on the river, and which could with advantage be experimented upon at Berri. The following varieties I believe are worthy of a trial:—Firstly, vines. The culture of currants, Sultanas, and Gordos has long passed the experimental stage, but now that grapes are selling at such high prices for wine and distilling purposes, I believe it would not be amiss if a few acres on the farm, both on the sandy rise and the harder flat land, were set apart, as far as the river is concerned, for the comparatively untried Doradilla, which is so well known for its productiveness in other parts of the State. Although the culture of the apricot and the peach has long passed the experimental stage, the same can hardly be said about the nectarine. The early common varieties, such as Cardinal, Fairchild's White, &c., are not ideal nectarines for drying, but Goldmine and Stanwich have been found to be excellent for that purpose wherever they have been tried. Two new varieties, Victoria, said to be similar to Stanwich, but maturing a month earlier, and Zelandia, said to be an improvement on Goldmine, should, with Goldmine and Stanwich, be given a trial. Turning to the the apple, it may perhaps be thought that as the Commonwealth annually exports about 1,000,000 cases to Europe, the market for this fruit is glutted, and that it would be useless to plant more. So far as early and late varieties are concerned, this is no doubt true, but if it could be proved that along the Murray valley such mid-season and early-export sorts as Ribston Pippin, Cox's Orange Pippin, Jonathan, and Dunn's Seedling would ripen two or three weeks earlier than they do in other parts of the State, then they would arrive in the London market when it was comparatively empty, and consequently realise satisfactory prices. Pears have long been grown with profit, but if such varieties as Beurre Bosc, Beurre Clairgeau, Poire de Berrioy's, and Winter Bartlett, which have proved such good croppers in other places, were given a place on the farm, they would perhaps prove themselves suitable to the district. Although it would be wise to test the different varieties of pears and apples both on the loose and harder land, it is probable that with good cultivation they would in the end give the best results on the stiffer land. Of all dried fruits the prune is most largely consumed. California boasts of over 10,000,000 prune trees, while the number that is grown in France and Italy is also very great. In Australia, however, the prune is not grown to the extent one would expect, and large quantities are imported every year. So far prune-growing has not proved a commercial success on the irrigation settlements along the Murray valley; but the fact that small groups of trees here and there bear regularly and well shows that their successful culture here is not impossible, but rather that the treatment they have received has not been suited to their requirements. Here, then, is a fit subject for experiment on the Berri Experimental Farm, and a few acres should certainly be tried. The varieties most commonly grown in California are Prune D'Agen, Fellenburg, Robe de Sargent, Sugar Prune, and Tragedy, and these varieties, with perhaps a few others, are worthy of a trial. One of the most profitable trees grown in California is the walnut, and last year the crop exceeded 8,000 tons. The common English walnut has been quite discarded in California, and has been superseded by French and local varieties. All varieties are grafted on to the Californian black variety, which makes the hardiest stock. It is claimed that grafted walnuts of good variety will yield a payable crop in five years, while unworked trees take twice that time. As the climate of California has many points of similarity with that of South Australia, and as the walnut finds a ready sale in the markets of the world, it would not be out of place to give it a trial at the experimental farm. The following varieties are said to do well in the hotter parts of California, and would perhaps do well here:— Franquette, Placentia Perfection, Eureka, and Neff's Prolific. Closely allied to the walnut is the pecan nut. The pecan thrives and produces fine crops of nuts in all localities throughout California, except near the sea coast, where, on account of fog and cool breezes, it is rather late in ripening. As with the walnut, only grafted varieties of good quality are worth growing, seedlings giving nuts of inferior quality. The most profitable varieties in California are the paper shell sorts, such as Stuart, Frotscher, Russell, and Success, and nuts of these varieties are at present selling at from 1s. 6d. to 2s. per pound in the United States. As the pecan thrives best in a hot climate, and as grafted trees are said to yield paying crops in six years, it should prove a fit subject for experiment. Another fruit that is at present booming in California is the avocado, or alligator pear, a subtropical pear-shaped fruit, said to be the best of fruits for salads. So great is the demand for this tree that Californian nurserymen are asking as much as £1 per tree for budded varieties. The best variety, which is said to be exceptionally hardy for a subtropical tree, is Harman, but whether it would survive the severe frosts of the Murray valley experiment only could tell. The tobacco plant should be given a trial in our experimental farm. Considering that tobacco of excellent quality was grown at Lyrup in the early days of that settlement, there appears no reason that it should not be grown now on other irrigated districts along the Murray. Many years ago I grew tobacco for a few seasons on a sandy flat in the Adelaide hills, and I feel certain that with proper culture such a variety as Havannah would do well on the red sandy slopes of Berri. As it gives an immediate return, it would no doubt prove a paying crop if 1s. per pound for good cured leaf could be realised. Many other plants are worthy of experiment— such as rice, which is now profitably grown under irrigation in California, and there are others with which I am not acquainted. So far the occupiers of irrigable land along the Murray have not taken kindly to dairying, and there seems little likelihood of its becoming very popular in the near future. Everywhere, both on the old and in the new settlements, more and more land is being planted to orchards. It behoves the Government to carry on a policy of vigorous horticultural experiments on irrigated land set aside for that purpose, and test the suitability of new varieties of plants and trees to the conditions of the river districts. If, after a series of thorough tests, it is demonstrated that certain varieties can be profitably grown under irrigation, the new lands, as they become ready for planting, could be largely planted with those varieties. This would relieve the pressure of competition from the older settlements, as well as assuring the success of the new, and give to irrigationists the assurance of a sure living." The paper was well received and discussed by Messrs. Stahling, Lewis, Phillips, Wishart, and Hughes, and on the motion of Mr. Phillips, seconded by Mr. Koska, the following resolution was unanimously carried:—"That the attention of the Minister of Agriculture be drawn to Mr. Arndt's paper, and that the Berri Branch of the Agricultural Bureau is fully in accord with the sentiment of the same."

Clanfield, July 25.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. W. Paull (chair), A. Orwell, P. Nelson, A. Correll, L. Orwell, C. Paull, H. Milne (Hon. Sec.), and three visitors.

Farming on Sandy Land.—Mr. A. Correll read a paper on this subject. He favored the tine cultivator for the first two seasons, as that implement broke more roots and pulled up more small bush than the disc. He would fallow after the shoots were well in hand, and would increase in the dressings of super. In the discussion that followed, members favored deeper sowing in the sand in dry seasons, as the surface of the sand soon dried. Mr. Paull favored fallowing the sandhills, his fallowed hill was quite wet now, although the season had been so dry. Some members favored the disc plough for working, as it cut so many shoots and worked the ground equally as well as the tine.

Claypan Bore, July 17.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. J. Gray (chair), S. Gray, H. Colwill, E. Colwill, D. McCormack J. Webb, J. Entwhistle, F. S. Tall (Hon. Sec.).

FENCING IN MALLEE DISTRICTS.—Mr. D McCormack read a paper on this subject. In this new country, he said, a great deal of fencing would have to be done. As a result of considerable experience, he had come to the conclusion that for utility and value a fence with few wooden posts had many advantages. In the North he had put up a sheep-proof fence 12 years ago, and it was as good to-day No. 10 galvanized wires were used, wooden strainers, and tee iron posts 4ft. 6in. long and 9ft. apart. He recommended two barbs and four plain wires, allowing 11in. between the two top wires and 7in. between the second barbed wire and the first plain one, with 6in. between those below. Strainer posts were put seven chains apart, and the height of the fence was about 3ft. 4in. In this district such a fence would be specially suitable, because only the strainers could burn. Doubtless the boundary fence would have to be made rabbit-proof. In the discussion which followed, Mr. Entwhistle recommended the use of more wooden posts to resist damage by stock. He had put these every chain with three iron droppers between. Mr. Gray would put strong gum strainers every 10 chains and 1¼in. by $\frac{3}{16}$in. tee standards every 9ft., using six wires, the top two 11in. apart, the next 8in. below, then 6in. and 5in. between the others. This would prevent the lambs breaking through.

RABBIT PEST.—A large number of methods for dealing with rabbits were discussed, and frequent use of the poison cart during the summer months advocated. Mr. McCormack considered that many methods of dealing with the rabbits were good, and advised members not to confine themselves to one means. Mr. Entwhistle strongly recommended fumigating. He had seen burrows where the rabbits had been completely destroyed by this method carried out in a thorough and systematic manner.

Coomandook July 12.

PRESENT.—Messrs. W. Ninnis (chair), A. S. and J Chapman, L. A., R. A, A., and R. B. Williams, M. P. Wilkin, E. A. Luxmore, W. W. Brown, C. E. W. Hillman, H. C. Hughes, O. J. A. Blucher, W. T. Legalley, C. M. Wilkin (Hon. Sec.), and six visitors.

FALLOWING —The following paper was read by Mr. O. J. H. Blucher :—" Fallowing is one of the most important matters connected with farming, but more so in the older districts than in the newly-opened mallee country. I am somewhat doubtful if fallowing new mallee land will pay directly, but indirectly undoubtedly it will, for one can get a larger area under crop in reasonable time. By burning or fire raking the stubble, followed by skim ploughing or cultivating, and a light dressing of super. and seed, probably a second crop can be secured equal, if not better, than that from fallow land. A great deal of labor will also be saved, which is no small item at the present. One disadvantage of fallowing is that the mallee shoots get an extra 12 months' growth without a check, which means extra work and expense, besides giving the mallee a chance to recover from previous fires and ploughing, especially if the stubble was not burnt the previous year But it will pay to go to a good deal of expense to fire rake the stubble before fallowing, and when done as early in the summer as possible, this will check the shoots, sweeten the soil, and kill a fair percentage of mallee altogether Fallowing should begin as early after seeding as possible, when the ground is in a wet state, and to get the benefit of all the winter rains it should be finished by the end of August, if possible. Land ploughed in spring is apt to be very loose, which encourages takeall. A share S. J. plough cutting a furrow of from 8in. to 9in. is the best implement, unless the ground is too sandy or stony, when the disc plough will probably do better work A depth of from 3in. to 3½in should be quite enough for this district. All the shares should cut to an even depth. If they are worn too much they are likely to leave a strip of ground unbroken in firm land. In this district, where the ground is naturally loose and fine, it can with advantage be left in a rough state till the early spring, when it should be cultivated or cross ploughed with a skim plough with mouldboards removed as shallow as possible. This results in a firm bottom with a loose mulch on top, which retards evaporation. If time and weather permit it is advisable to harrow again before harvest, or any time during the summer after a rain. This helps to a great extent to conserve the moisture, which is one of the main factors in fallowing. Before sowing, the land should be again cultivated, after a rain if possible, drilled, and then harrowed." Members generally favored fallowing to a depth of from 3in. to 3½in. It was advisable to turn the fallow back with a skim plough, which pulled out stumps loosened by the plough and assisted in the retention of the moisture.

Coonalpyn, June 13.

(Average annual rainfall, 17·49in.)

PRESENT.—Messrs. Wall (chair), Venning (two), Bone, Samuel, A. Fidge, Pitman, Cronin, J. Hill, J Flint (Hon. Sec.), and four visitors.

PLOUGHS.—Mr. G. E. Venning read a paper. The specific function of the share plough, he said, was to turn the soil, and it was well to bear this in mind. The work could not be well done if the beams were bent, the ploughs strained, or the shares blunt, or badly set on the foot on account of a bad mould or a false stump not being properly fitted in the socket. The old weight pressure stump-jump plough was better than the bridle draught implement, as the former was easier on the horses, and wear and tear was not so great. Small ploughs did better work than large. A four-furrow implement was best. The disc cultivator was good for use where there was rubbish to contend with. The farmer with limited capital starting in scrub land was advised to procure a disc cultivator for working his land for the first two years. After this a four-furrow share plough should be used on the land, whether it was for fallow or crop. Nothing but the best make should be purchased.

PIGS.—Mr. H. Bone dealt with this subject in a short paper. While pigs would exist on practically any offal, he said, they would not do well unless they were well and carefully fed. The progeny of a Tamworth sow crossed with a Berkshire boar would be found most profitable. The Tamworth grew to a good size, was fairly hardy, and a good bacon pig, and the Berkshire was a good doer and grew fast. Proper care and attention were essential

Forster, June 14.

(Average annual rainfall, 10in. to 11in.)

PRESENT.—Messrs. C. Hayman (chair), W. J. and T. Searle, J., F., and W. Johns, J. G. Whitfield, P. Purdee, T. and G. Retallack, C. P. Payne, E. Towill, W. Sears (Hon. Sec.), and four visitors.

HANDLING FARM HORSES.—Mr. W. Searles read a paper in which he said care and attention given horses from the time of foaling until breaking was amply repaid. Colts should be weaned at six months of age, and if they were tied up, it would be found that they were much quieter when being broken in. For breaking he advised the use of a crush pen. After the animal had been roped, the winkers should be put on. A piece of white cloth on a stick should be rubbed over the neck and ears of the beast if trouble were experienced, the winkers being worked up the neck and down over the ears. When an attempt was made to put them up over the horse's nose, there was a danger of the operator being struck with its front feet. A plough rein should be attached to each ring of the bit, and after the animal had been driven for about an hour the harness should be put on, particular care being taken to see that the collar fitted. When harnessed, it should be placed in the shafts of a waggon alongside a steady, reliable horse, capable of drawing the load by itself. The best age for breaking was three years, but the horses should not be worked for more than half a day at a time for the first 12 months.

FENCING.—Mr. J. G. Whitfield gave the following specification for a fence :—Posts, pine, cut green, barked, and seasoned for about 12 months, not less than 4in. in diameter at small end, and placed 18in. in the ground, 10ft. apart. Top wire 3ft. 10in. from ground, second 2ft. 9in., and bottom 1ft. 9in. The centre wire would then be of correct height to carry 3ft. wire netting. Members generally preferred the white mallee for posts.

Forster, July 19.

(Average annual rainfall, 10in. to 11in.)

PRESENT.—Messrs. W. G. Retallack (chair), W. J. Sears, C. Payne, C. Hayman, J. Stone, T. and W. C. Retallack, J. Searle, R. Whitfield, T. Searle, G. Searle, J. Johns, C. Payne (Hon. Sec.), and three visitors.

AGRICULTURAL LABOR.—Mr. T. Searle read a paper in which he stated that a farmer holding 1,000 acres, with 500 acres cleared, and possessing a five-horse team and the necessary implements, could keep two men employed. He could deal with between 230 and 240 acres with the team mentioned. Of this, 20 acres would be required for hay, and 20 acres sown to oats for feed, leaving 200 acres for wheat, which, on an average yield of 8bush., should return 530 bags, worth £260. Seed, super., &c., would involve £70, which left a balance of £190 to pay wages, which amounted to £90 per year per man, and recompense the farmer. He would be better off if he put in 180 acres himself, which, after deducting the area necessary for providing horsefeed, would return wheat valued at £185. Taking the cost of seed and super., £60, from this, left £125. It might be necessary to employ a man for one week at hay-carting and two weeks at wheat-cleaning, which at £2 per week would mean a further expense of £6, but there was still a balance of £20 in favor of cropping the smaller area. During the past two seasons the average yield had been less than 8bush., consequently the farmer's return was somewhat lower than that given above. Mr. W. J. Sears thought much of the work on a 1,000 acre farm would be neglected unless the farmer employed a man. Mr. C. Hayman also thought it would pay the farmer to employ labor. Messrs. J. Johns, C. Payne, and W. G. Retallack agreed with the paper, and thought that it would pay a small farmer better to put in less crop than to employ men at high rates of wages.

FARM GARDENS.—Mr. C. Payne read an article on this subject from the *Journal of Agriculture.* He had successfully grown vegetables with bore water, especially tomatoes and melons. Mr. W. Searle thought it better for the farmer to purchase vegetables than to try to grow them. Mr. J. Johns found that where bore water was used on cabbages they were affected with blight. Mr. J. Searle had successfully grown pumpkins under old rotten chaff heaps without water. Many vegetables and fruits of good quality had been produced on his farm.

Hooper, July 11.

(Average annual rainfall 14in. to 15in.)

PRESENT.—Messrs. J. R. Beck (chair), C. B. R. Wright, E. G. Colton, G. G. Pitt, A. W. Lawrie, R. J. Chenoweth, J. Boyce, W. Boyce, W. Sweetmann, C. S. Hall (Hon. Sec.), and three visitors.

FARM IMPLEMENTS.—The following paper was read by Mr. Wright:—"The success of a farmer depends largely upon his wisdom in selecting and the care he takes in protecting his implements. When purchasing he should not depend too much on hearsay. An implement that gives satisfaction on one class of land may be useless on another; and one that is good on fairly clean land will not always work successfully where the stumps are prominent or sometimes even where it is hilly. Farmers should avail themselves of the opportunity of getting an insight into machinery at the agricultural shows and field trials, especially the latter, as they can there be seen to better advantage. An unsuitable implement is not only waste of capital, but often the cause of a considerable waste of time at most inconvenient periods. For the protection of implements it is essential to keep them under cover, as the varying conditions of weather have a very bad effect upon them. If implements constructed of steel are left out, the paint will soon crumble off and allow the steel to rust. The nuts will not only become set on the bolts, but the threads will rust and be rendered weak. When one has finished working a machine for the season all the old grease which has been allowed to accumulate should be removed while it is soft, and a coat of blacklead is very beneficial to wearing parts. Note should be taken of any necessary repairs or missing parts, so that one's time is not wasted when one wishes to work the implement again. All implements constructed of wood when put away in the shed should have a good coat of boiled linseed oil rubbed into them. This will not only preserve the wood, but will make it much easier to paint. This can be done in a very short time, and it is surprising what a little oil is required. When taking a machine out again give it a good coat of paint. This will protect it from the weather while the machine is in use. This is especially necessary with harvesters. They are constructed with a good deal of light wood, and unless kept oiled and painted frequently the dampness will cause the wood to swell and warp. Do not buy paint ready mixed in 2lb. tins; this will prove too expensive. Procure white lead in 56lb. drums and the oil in 5gall. drums, get the colors, and mix the paints. This will be much cheaper, and in my opinion a better paint. To preserve the oil keep it airtight. The white lead will keep for any length of time if it has 2in. of water on it."

Lameroo, June 21.

(Average annual rainfall, 16·55in.)

Present.—Messrs E. J. Trowbridge (chair), O'Connor, Jas and K. Cameron, F. W. Eime, Marshall, Lehman, Leckie, Wray, C. R. Eime, Ross, Thyer, Koch (Hon. Sec.), and one visitor.

Fodder Crops.—Mr. Marshall read a paper on this subject. For growing hay he recommended the selection of a piece of rich flat land, which should be well ploughed in July or August. It should be harrowed to a fine tilth, and cultivated and harrowed several times during summer. A good tine cultivator should be put over it during the following season, and 2bush. brown Partridge peas and 100lbs. of super. per acre drilled in as deep as possible, together with 1lb. of lucerne seed, which would develop a fairly strong growth by the time the land was again left out for pasture. A yield of 20bush. per acre could reasonably be expected from the peas. The cost of the seed, 2bush. at 3s. 6d., 7s., and super., 100lbs., 5s., deducted from the value of the crop, *i.e.*, 20bush. at 3s. 3d., £3 5s., left a net return of £2 13s. per acre. After the peas were harvested the land should be cultivated, say during March, to encourage the growth of weeds In May it should be skim ploughed to a depth of about 2½in., and then half the area drilled twice with ¾bush. of either King's Red or Golden Drop wheat and 60lbs. of super. each way The other half should be drilled twice with 60lbs. of super. and 2½bush. Calcutta oats per acre. The return should average 2 tons per acre. The following season it could be grazed or fallowed. He had tried English rib grass, Italian rye grass, and prairie grass with good results, but the best for this district was the Mount Gambier spear or barb grass. Last year he sowed 30 acres with lucerne when drilling oats for hay, and this had produced some very good feed. Half an acre was covered with a thick coat of stable manure and sown with lucerne and peas. A good crop of the latter was secured, and the lucerne promised well The best soil for this was just at the foot of the sand rises. Mangolds had been broadcasted on land cultivated to a depth of 6in. and heavily dressed with stable manure, and a return of about 10 tons to the acre was secured. Thousand-headed kale rape, mustard, sorghum, maize, swedes, red and silver beets might well be given a trial in this district. The Long Red and Turnip beets did well, and there appeared no reason why sugar beet could not be profitably grown here. Mr. F. W. Eime preferred peas for fattening sheep and lambs. Lucerne tended to cause trouble with the sand, as the stock ate it close to the ground. It was better grown in small plots, irrigated, and fed cut. Mr. Marshall's estimate of the value of a pea crop did not take into consideration the cost of labor involved. Several members preferred hay as the best and surest fodder to grow. The Chairman said barley grass was doing well on his farm. Mr. Marshall, in reply, contended that whilst a good crop of hay could be grown on fallow, better results attended the growing of peas

---

Lameroo, July 19.

(Average annual rainfall, 16·55in.)

Present.—Messrs. E. J. Troubridge (chair), Cameron, Jericho, Blum, Leckie, Lehman, Kumnick, C R. Eime, Wray, Ross, A. J. A. Koch (Hon. Sec.), and four visitors

Fallowing.—The Chairman read the following paper on "Fallowing":—"I feel sure that there is not enough fallowing done in this district," he said, "and what is done is not worked sufficiently afterwards. Although we have not much difficulty with weeds in this new country, I would advocate cultivating all fallow in the spring, and leaving the sandy soil rough after the cultivator to prevent drift. Heavy flat land can be harrowed down fine after cultivating. In respect to depth to fallow, different soils need different treatment. I find about 3in. quite deep enough for my land. I would like to state a few facts, which, if put into practice, will greatly help in growing wheat successfully. By fallowing early we can conserve more moisture, and June and July are the months that under ordinary circumstances will give the best results. Of course, this year somewhat upsets the practice of fallowing early, and one cannot say what will be the best to do. I am of the opinion, however, that it is better to do a little fallowing, even though the land is dry, and then work it back again when the rain comes. Light sandy stubble land should not be fallowed, as this encourages takeall. Such land should have at least a year's spell after cropping before fallowing again. Bush on the land should be cut and cleared off before fallowing. Not only can the work be done better, but after it is done it will give better results, as green shoots in fallow take the moisture that should be conserved for the wheat, I am sure that the Pinnaroo district when properly fallowed and worked will figure very prominently as a productive district of this State." In the discussion which followed members unanimously agreed that fallowed land well worked was essential to the safe growing of crops in this district.

Monarto South, July 19.

(Average annual rainfall, 14in. to 15in.)

PRESENT.—Messrs. G. Patterson (chair), A. P. Braendler, J. and H. Frahn, G. H. Gogol, A. J. and R. Hartmann, A. Harper, H. H. Hein, H. E. Kuchel, A. Patterson, J., G. H., R., and G. Paech, A. Schenscher, F. C. Thiele, E. Tillbrook, G. Thomas, J. Daley, J. Hutton, A. Forbes, C. F. Altmann (Hon. Sec.), and six visitors.

DESTRUCTION OF FOXES.—In a paper on this subject, Mr. J. Hartmann said the cheapest way of dealing with the fox pest was poisoning. The method he adopted was, when killing a sheep, to take out the pluck with a fork, care being taken not to touch it with the hands, and cut it into pieces about twice the size of an egg. These should be taken on a spade to places where the foxes were likely to visit. At each of these a hole about 3in. deep should be dug, and into this a bait dropped. This should be pierced with the knife and sufficient strychnine to half cover a threepenny piece inserted, and the bait partly covered with soil again. Dead lambs also made good baits, but remaining portions should always be buried, as dogs and cattle might pick them up. Some members thought birds were preferable as baits, as dogs would not touch them, but Mr. A. Hartmann reported having lost a dog in this way.

Monteith, July 14.

(Average annual rainfall, 14in. to 15in.)

PRESENT.—Messrs. D. J. Travers (chair), J. F. Connell, F. S. Bradford, A. A. Wells, J. Ferries, J. Rowan, sen., W. G. Gunn, W. H. Carter, Kirby, sen., A. Clark, J. W. McCulloch, G. Fraser, J. McAuliffe, L. Bell, T. Kelly, W. Kirby, W. S. T. McCulloch, C. A. Bentley (Hon. Sec.), and a number of visitors.

AGRICULTURAL BUREAU WORK.—The Secretary to the Advisory Board of Agriculture addressed the meeting on Bureau work. In conversation with owners of the irrigation blocks that day, he had learned that great differences of opinion existed as to the best means and times to irrigate and the best crops to raise, and that members generally seemed to be in agreement in the view that very little of the potentialities of the reclaimed swamps was known. He therefore strongly urged that some experimental work should be undertaken by the members for the Branch, to be under the supervision of a committee appointed for that purpose. At present individual members were doing some experimental work, but without definiteness, and without keeping careful records, so that results could be tabulated and averages worked out to show the effect of certain practices over a number of years. Mr. Nicholls also urged the members to establish the work of the Branch on a sound and businesslike basis. Punctuality in the commencement of meetings was essential if the interest of the best men, to whom time was money, was to be secured and retained. Good discussion followed. An experimental committee was appointed to prepare a plan of work for approval by the Branch, and to supervise same and to keep the records. A programme committee was also appointed, and a quorum. It was decided that meetings should commence punctually at 8 o'clock in future, and other details, such as finance, &c., were put upon a sound footing. Members were enthusiastic in regard to the possibilities for effective Agricultural Bureau work on the fertile reclaimed areas on the Murray.

Parrakie, June 14.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. F. J. Dayman (chair), A. J. Beelitz, H. Deiner, O. and C. Heinzel, A. F. Dayman, J. Temby, R. L. Beddome, R. E. Jose, N. and S. Good, T. Lewis, M. J. Cooney, J. O'Hara, A. C. Hameister (Hon. Sec.), and two visitors.

PIGS.—In a short paper on this subject Mr. J. O'Hara advised every farmer to keep a few pigs to consume that which would otherwise be regarded as waste. When purchasing, animals about eight weeks of age and well grown should be procured. Pure-bred pigs did not grow to such a size as the crossbreds. He favored the Berkshire-Tamworth, which made excellent bacon. As they required a good deal of attention, it was unadvisable to breed more than one litter at a time. They should be sold at eight weeks of age. Breeding, however, was not profitable unless plenty of feed was available. The best time for breeding was between May and July, when a good market was generally available. Some members thought the Berkshire-Essex cross pigs fattened more quickly than the cross recommended by the writer of the paper, whilst others preferred the Poland China-Berkshire cross

HORSES' SHOULDERS.—Mr. F. J. Dayman contributed a short paper in which he said care should be taken to see that the collars fitted the horses properly. As the animals fell away in condition, it was important to see that the collar did not become too loose. A piece of bran bag could be put under them in this case. When the shoulders became sore, the best method to adopt was to loosely stuff an old collar with horsehair, and line it with a bran bag; the trouble could then frequently be got over without the horses being spelled. The shoulders should be brushed well every morning, and before they started work after dinner. Some members favored leather lining to collars.

Parrakie, July 12.

(Average annual rainfall, 16in. to 17in)

PRESENT.—Messrs. F. J. Dayman (chair), F. W. Gravestocks, S. R. and N. J. Good, C. and O. Heinzel, T. Lewis, J. O'Hara, F. W. Randell, W. E. Threadgold, J. T. Temby, M. J. Cooney (Hon. Sec.), and four visitors.

CARE OF HARNESS.—In initiating a discussion on this subject, Mr. Congdon recommended unpiecing all harness and washing it with soft soap. Vacuum oil should then be applied with a stiff brush, and the harness hung until the oil dried well in. Mr. Temby preferred vacuum oil for heavy harness, as it soaked well into the leather. Messrs. N. J. Good, Lewis, and O'Hara favored neatsfoot oil. Vacuum oil contained properties that prevented it penetrating the leather. In reply, Mr. Congdon expressed the opinion that these properties acted as a filling, added to the appearance of the leather, and did not prevent the penetration of the oil.

Pinnaroo, July 19.

(Average annual rainfall, 16·74in.)

PRESENT.—Messrs. P. J. Edwards (chair), A. W. Burman, F. G. Bonnin, J. Docking, H. E. Dibben, Roy Edwards, L. M. Ferguson, L. M. Hannaford, M. Kelly, H. Ledger, J. Letheby, M. McCabe, E. H. Parsons, J. Pitkin, C. A. E. Schiller, J. Scales, W. and H. Venning, G. Wilson, P. H. Jones (Hon. Sec.), and one visitor.

SHEEP AND FENCING.—The following paper under this title was contributed by Mr. Ledger:—" This subject arose out of a discussion on 'Sheep on the Farm and Weeds,' by Mr. Kelly. It was clearly demonstrated that we are to have our full share of almost every variety of weed, and on a good many farms they were proving a drawback to crops at present. It is also fully admitted that the time has come when farmers should fallow. It is a very difficult matter to eradicate weeds by cultivation alone, more especially in stumpy country. Therefore we must have sheep, and must consider the question of sheep-proof fencing. I think that ultimately land in this district will be cropped once in every third year, so that the farm should be laid out with this object in view. Also that every paddock should lead home, so that no time will be lost in going to and from work. This can be done, at the same time having the homestead near the road. Water can then be laid on to each paddock with little expense. I consider it important that stock have free access to water. For a division fence I like posts of red gum, or if pine be used they should be split out of the butts of old trees, and all posts allowed to thoroughly dry before being put in the ground. One such post and four iron posts to the chain, with five plain wires and a barb on top, the distance between wires 5in., 6in. 7in., 8in., and 10in. should make a good fence. Keep wires well strained, for bad fences make rogues of all stock. We are in a dog-infested country, and the question arrises as to whether it will pay to dog-proof. I have been in search for information, as I had no previous experience in this line. To put up a fence I should like to see would cost £80 a mile; this would be only an ordinary dog-proof fence. I have full details of material and cost, which I should be pleased to let any member have. I have also some considerable information as to the profit derived from sheep, page 1408, July *Agricultural Journal*. G. H. Wright, of Hawker, has an article on this matter, which corresponds with other information I have on this subject. To fence a thousand acres would cost £400; 250 ewes for this area would return a net profit of, say, £85, after allowing 8 per cent. interest on outlay. Some may say this would not pay, but the question is will it pay to be without sheep taking into consideration the convenience of having them to run over the fallow when it would not be convenient to cultivate it. Much feed is going to waste. Sheep would reduce the butcher's bill by 50 per cent. Personally, I feel it would be money well spent. Some have suggested yarding sheep as an alternative, but this would mean lost time, damaged wool, meat driven off, and then the sheep would often be in the yard when they ought to be feeding. Further, as our country will grow lucerne, it will be worth our while to rear lambs, and these cannot be yarded. There is the question of fencing the hundred, which I think worth considering. There is no doubt the outside settler should be considered. He is always working against great odds and is on the border of a dog-infested area. I refer principally to the south, which must remain for a long time a dog-infested waste. I think the Government might be approached on this matter, but I should say let every farmer keep the dog-proof fence in view when putting up his ring fence." Good discussion followed. Mr. E. H. Parsons had been advised by an experienced sheepfarmer to use wire netting in lieu of the usual six wires. It was more satisfactory, and kept out rabbits. Mr. F. G. Bonnin said it sounded well on paper to fence the hundred, but there was a considerable area of scrub within the boundary which acted as a fine harbor for vermin. Mr. Schiller did not think it would pay to individually put up dog-proof fences. By keeping sheep a considerable quantity of cultivating was obviated. Mr. Scales thought the cost of fencing allowed in the paper was too much for the average farmer. Three wires would be quite sufficient if regular attention were paid to the fence after its erection. Mr. W. Venning also maintained that the fence could be put up at far less cost than figured by Mr. Ledger. He considered a wooden post every half chain with a strong iron standard between would make a very good fence. Mr. Burman raised the question of disagreement with neighbors; one might be disinclined to make his portion dog-proof. He questioned whether such a fence as advocated by Mr. Ledger would be of any advantage. Mr. Docking recommended alternating plain and barbed wires. While not altogether dog-proof, he had known such a fence to act very well. Mr. M. Kelly said that where netting had been put down, adjoining a sand ridge, in a few years a couple of feet had been submerged. In replying, Mr. Ledger said in respect to fencing the southern boundary, some dogs would be shut in, but as there would be no further influx these could very soon be killed. To prevent trouble from sand drift he would leave a chain of standing mallee on the outer edge of each sandhill. The Government average cost of a dog-proof fence was £80 per mile, but probably a less elaborate fence would meet the needs of the individual farmers. Dogs and foxes would climb over a straight fence, but if the top barbed wire leaned outwards this acted as a check.

Renmark, June 17.

(Average annual rainfall, 10·93in.)

PRESENT.—Messrs. J. S Huggins (chair), F. Cole, M. B. Geneste, H. S. Taylor, R. Nutall, C. J. Everard (Hon Sec.), and one visitor.

FRUIT-DRYING.—The general opinion of members was that in the majority of cases where racks were found unsatisfactory the trouble lay in that too large a quantity of fruit was put on the racks, or the fruit was removed before it was thoroughly dry. If the fruit were spread lightly it dried much more quickly.

MANURING FRUIT TREES.—In initiating a discussion on this subject, Mr. Muspratt said different soils needed different treatment, and every grower, if he wished to obtain the best results from his labor, must do a certain amount of experimental work. The average grower did not manure deeply enough. His own practice was to fertilise when furrowing out for the second irrigation, running the manure into the bottom of the furrow, by means of a hopper machine attached to the plough. The earth was then thrown back into the furrow, and the second furrow thus formed used for the irrigation. He applied

2cwts. or 3cwts. of bonedust, bone super., blood and crushed bone, or hashmagandy, with 1cwt. of sulphate of potash if the show of fruit warranted the application of potash. Potash was applied for the sake of the fruit primarily, and not for the plants, and the reason for leaving the application of manure till the second irrigation was that by this time it was possible to judge whether the crop would be worth an expenditure for potash. Green manuring was regularly practised by Mr. Muspratt, especially on the land carrying citrus trees, which was treated in this way every year. The best crop of green manure was peas. One hundredweight of super. was sown with the peas in addition to the general manuring mentioned above. Nitrate of soda, at the rate of about 2cwts. for vines and 1cwt. for citrus trees per acre, was applied when the plants began to show signs of sickliness. The promiscuous mixing of manures was a dangerous practice, involving, in ignorant hands, a serious risk of neutralisation of values. If several kinds of fertilisers were tried, the safer plan was to apply them separately It was not a good plan to use the same class of manure year after year. He recommended bonedust one year, super. the next, blood and crushed bone the next, and so on, but bone super most frequently. Horse manure was excellent for citrus trees. The soil was made more friable thereby, its humus content increased and heavier yields of fruit secured, but there was a tendency for oranges so grown to be thick skinned. Sheep droppings, if in good condition, made a valuable manure; good results followed its use after a season of succulent herbage, but if the sheep had been passing through a droughty period the manure was too hot and tended to dry out the land. The value of gypsum had long been established beyond dispute. But even gypsum could be overdone, its excessive use causing the soil to dry out and become parched. A similar effect was produced by the too free application of wood ashes. Better results had followed the use of lime. These dressings acted beneficially by affecting the mechanical texture of the soil and making available for plant use the fertilising elements it contained. They should not be ploughed under, but worked into the surface soil As a general practice, deep ploughing might be regarded as being as essential as manuring. Gum trees and peppers, so often used for windbreaks, were great robbers of the soil, and trenching would often be necessary to prevent their roots injuriously affecting the adjacent trees or vines. Mildura settlers had given up the practice of turning under peas in the green state, as they had discovered that they had a tendency to sour the soil. They were disked up in the green state first and allowed to dry before being ploughed under. But no necessity had been found for this in Renmark. Gypsum was valuable as a remedy for brown scale. For this purpose it should be dusted on the citrus trees when the fruit set. There was, as a rule, neither dew nor rain at that time, and a still, hot day should be chosen for the application. For the last three years Mr. Muspratt had applied sulphate of iron to his citrus land at the rate of 1cwt. to the acre. The use of this salt was generally advised when the leaves showed a tendency to "yellow." He had been troubled with "hard pan" about 2ft. below the surface of his citrus slope, and last season resorted to dynamite, using a case and a half on 3 acres. Holes were bored into the pan and charges exploded between the trees. Very marked results were already noticeable. Previously the roots had never been able to pierce through the pan. The entrance afforded by means of the explosives should greatly extend the feeding area and add to the vitality of the trees The average returns from his vines were—Sultanas, 1 ton per acre; currants, 1¾ tons; Malagas, 1¼ tons; and Gordos, 1 ton per acre.

Present.—Messrs. Snell (chair), Badge, Heusler, B. Mibus, J. B. Thiele, Dohnt, and Twartz (Hon. Sec.).

Preserving Eggs.—Mr. Badge read a paper on this subject, in which he advised members to preserve eggs when they were selling cheaply and market them when the prices rose. He pointed out that the shell of the egg was porous, and the white content was evaporated through these pores as the egg became older. A cheap and effective preservative was vaseline, which could be smeared over the egg, it then being wiped with a cloth. The eggs should be packed in dry sand, the small ends being upward. The case in which they were packed should be turned at intervals of eight or nine days. Another method was to smear the eggs with glycerine (oil of sugar) and place them in waterglass (sodium silicate). Pickle was frequently made from a solution of 1lb. of lime in a gallon of water, and eggs could be kept for months in this. He had kept eggs for seven months by smearing them with mutton fat and packing them in salt in a glass jar. They turned out perfectly good. He intended covering a few by way of experiment with some greasy substance and placing them in well water which on analysis showed the presence of sodium calcium, magnesia, and potassium. Solutions of soap and other colloids were found to exert a similar effect, and best results in this regard were secured from a mixture of waterglass and a 10 per cent. solution of resin soap, with a very slight excess of soda. Mr. Snell mentioned that he had successfully kept lemons for a considerable period by smearing them with vaseline

SOUTH AND HILLS DISTRICT.

Blackwood, July 14.

(Average annual rainfall, 27in. to 29in.)

PRESENT.—Messrs. W L. Summers (chair), P. H and D. Williams, Ashby, Gamble, T. C. A., A. W., and A. A. Magarey, Sibley, Philps, Eglinton, Scherer, Nicolle, L. and H. Sullivan, Winser, G W. Summers, Hilfers, James, Phillips, Savage (Hon. Sec.), and five visitors

CONTROL OF ORCHARD PESTS.—The Hon. Secretary read a paper which will be found printed on page 41 of the current issue

Cherry Gardens, July 15.

(Average annual rainfall, 35·03in.)

PRESENT.—Messrs. H. Jacob (chair), C. Lewis, G. Hicks, J. Lewis, C. Ricks. T. Jacobs, sen., J. Tozer, T. Jacobs, jun., H. Lewis, A. Broadbent, S. W. Chapman, E. Broadbent, A. R Stone (Hon. Sec), and two visitors.

PIG-KILLING AND BACON-CURING —Mr C. Ricks read a paper on this subject. The method of killing a pig that he recommended was to place the animal on its back and make a slit of about 4in. in length in its neck parallel with the jugular vein. Whether the water was of the required temperature for scalding or not could be determined by placing a small amount of blood from the pig into it. If this diffused over the surface and did not sink, the pig could be safely placed in the water. Water at the required temperature would also throw a clear reflection When the bulk of the hair was off the pig, the animal should be taken out and scraped with a short-handled hoe, or a piece of hoopiron with the ends fixed into pieces of wood, to take the hair off the head and legs. The next move was to rub soap and warm water on the beast until a good lather was secured, when it should be scrubbed off with half a brick. After this the carcass should be hung and table salt should be well rubbed all over it Whilst the animal was still hot the inside, eyes, and jaw should be taken out. In favorable weather the killing was best done during the afternoon of one day, the cutting receiving attention early the next morning. But in warm, sultry weather it was safer to cut the carcass at once and salt it whilst hot The disadvantage of this method was that the meat was flabby, and so more difficult to handle. He used 4lbs. of white sugar and 2lbs. of salt to 100lbs. of meat for curing, rubbing the rind first and sprinkling the meat inside. The second day ¼lb. of saltpetre and 4lbs. of salt should be added. The sides should be placed alternately one on the other daily for a week, and then every other day for 14 days. The salt and sugar should be well pressed and rubbed into the meat, and the brine pressed out of the hams. It should be ready for hanging at four weeks. Any salt adhering to the sides should be washed off and brown sugar rubbed over them. After it had dried the bacon should be placed in flyproof calico bags and hung in a cool, dry cellar for six months, when it should turn out of first quality. In discussing the subject, Mr. T. Jacobs, sen., advocated sticking the pig whilst it was standing. For scalding large animals he would place them on a wooden stool or table and pour boiling water from an ordinary watering can on to one-half of the carcass at a time. He always made a practice of cutting whilst the bacon was still warm, and the results had always been successful. Mr. Tozer said it was better to have the water for scalding slightly under rather than over the required temperature, as when it was too hot the greatest difficulty was experienced in cleaning the carcass. It was better and easier to add hot water if required.

Gumeracha, May 20.

(Average annual rainfall, 33·30in.)

PRESENT.—Messrs. B. Cornish (chair), D. Hanna, J. B. Randell, J. Porter, and W. B. Randell (Hon. Sec.).

HORSES' HOOFS.—Following on the reading of an article from the *Journal*, Mr. D. Hanna said it was the duty of all shoeing smiths to study the hoof of the horse and not to pare away more than was absolutely necessary to ensure the shoe fitting. Too much cut away from the outer side was likely to make the horse pigeon-toed. Fitting a red hot shoe resulted in the hoof becoming brittle. It was quite unnecessary to trim the feet of foals. Rasping the hoof and paring away the frog should not be permitted. Mr. Porter had treated with axle grease hoofs which had a tendency to crack; this toughened the hoof. Horses reared on level country developed large hoofs, whilst those bred in hilly districts developed smaller hoofs, a provision of nature to secure surefootedness. Mr. B. Cornish recommended farmers living a distance from a shoeing smith to have a small forge and tools. The removal of a shoe, or the driving of a nail or two to tighten a loose one, would not take nearly the time that was involved in the journey to and from the smith. He believed in trimming the frog slightly to prevent stones becoming jammed between it and the shoe. To prevent horses striking, the outer part of the hoof should be trimmed down more than the inner. Mr. J. B. Randell did not think foals' hoofs needed trimming. Unskilled shoeing he thought would ruin a horse.

Gumeracha, June 16.

(Average annual rainfall, 33·30in.)

PRESENT.—Messrs. B. Cornish (chair), J. Porter, D. Hanna, H. W Norsworthy, J. Monfries, J. B. Randell, A. E. Cornish, A. H. Cornish, and W. B Randell (Hon. Sec.).

FRUIT-GROWING.—Mr. J. B. Randell gave a very able and interesting address on the subject, "Does the Present Outlook of the Fruit-Growing Industry Justify Further Planting." In reviewing the present situation he said that the market for fruit in the old world had been poor, owing to the second-class produce arriving in poor condition. He spoke very strongly against growers sending any other than the very best for export. He was very hopeful for the future of the industry, but insisted that anyone going in for it must be in downright earnest, have a love for the work, and strenuously endeavor to produce the very best. Mr. H. W. Norsworthy, who had had some experience in packing, said that in a great many instances the fruit was picked and packed before it had matured. As an experiment, he had put aside some fruit that he considered insufficiently matured, and in two month's time it was rubbish compared with properly matured fruit. He recommended orchardists to turn their attention to stone fruits, especially plums. Other speakers were of the opinion that marketing poor quality fruit operated against the industry. The growing of plums and prunes should receive more attention.

Hartley, June 16.

(Average annual rainfall, 15in. to 16in.)

PRESENT.—Messrs. B. Wundersitz (chair), W. Bermingham, H. Cross, A. Wundersitz, D. Clark, W. Brook, B. Klaebsch, T. Phillips, G. Phillips, G. Hill, C. Klencke, S. Beavis, S. Pratt, J. M. Hudd, J. Hudd, D. F. Westwood, F. Lehmann, F. Bruns, J. L. Forbes, and J. Stanton (Hon. Sec.).

CLEARING.—In a paper dealing with the advisableness of clearing the land in this district, Mr. W. Bermingham said the farmer had to deal with bluestone reefs, and old gum stumps cut off a few feet from the ground some years ago. The stones should be picked and deposited in large heaps or in water washes. In addition to the enhanced value of the land when this was done, there was a saving in the wear and tear on implements, which should be considered. The stumps could be burnt off, cut level with the ground, or, better still, grubbed. Disc ploughs and cultivators were best for use in stony land, and he had found it a good practice, when outcrops of stone were encountered, to make a fire on them, after which they could be easily broken off. Members generally agreed with the ideas of the writer of the paper. The best means of getting rid of old stumps was burning with the aid of cocky chaff.

Inman Valley, June 6.

(Average annual rainfall, 26in. to 27in.)

PRESENT.—Messrs. J. R. Russell (chair), J. W. Crompton, H. J. and M. J. Meyer, A. McCoy, G J. Barratt, H. G. Allert, T. G. and R. Rose, H. T. Martin, H. I. and R. J. Martin, H. J. Jagger, R. A. Mayfield, H. M. Parsons (Hon Sec.), and three visitors

PRUNING FRUIT TREES.—The following paper was read by Mr. J. W. Crompton:—" Pruning is an art whereby the strength of the plant is directed into certain channels, bringing about, in the case of the young tree, the quick development ot branches desired, and in the case of the older tree the satisfactory bearing of fruit. In nature fruit is born for the sake of reproduction, the seed being the main object. The pulp is there, so that animals and birds will assist in spreading the seed, and provide a suitable bedding for its germination. Men have increased the proportion of pulp and sugar, and modified the flavor by cross fertilisation, selection, tillage, and pruning. If left unpruned most fruit trees grow to a considerable size, bearing greater average crops than a pruned tree. But the crops are irregular, and the fruit often very small, and lacking sweetness and juice and, perhaps, flavor. In the orchard the trees are mutilated for the sake of increase in the total weight and regularity of the crops to be obtained from a certain area of land. The objects aimed at in pruning are—First, to keep the tree of a size and shape that will allow of easy picking, &c., without damaging the tree, and effective spraying, which is very important. Second, to keep the tree in a healthy vigorous condition; setting and holding its fruit. The weakly tree sets its fruit readily, but either it drops off, is lacking quality when ripe, or the tree is made weaker still. The tree that is growing very strongly does not set its fruit in sufficient quantity. The aim is to gain the medium between these extremes. The same applies to separate shoots, and dealing with those is the main problem in pruning. Every live shoot cut off in the winter means greater vigor thrown into the rest of the tree. In the summer the opposite obtains. All plants grow more vigorously on upright shoots than horizontal ones; they grow strongest at the top and where there is most light. In view of all these points it has been found that it is desirable to shape the tree, to have all its main branches curving evenly outwards and upwards from a single stump, thus forming a sort of cup shape, hollow in the middle, with the short lateral growth on these main branches from the bottom to the top. If the centre of the tree is not kept open, and the light cannot get at the lower parts, the lateral growth, which bears the fruit, will become weak or die, and the crop is born so much higher up and more out of reach, and is very likely not there in such quantity. The ideal shape for a fruit tree is an open cup shape with side growth all the way up the branches This cup shape is varied with the different kinds of trees, according to the rigidity of the branches. The more easily they bend the more upright they should be trained. The peach, the apple, and the apricot have stiff branches and are trained in the shape of a rather squat teacup. The pear, the plum, cherry, and the almond are trained more in the shape of a long wine glass, with the branches spreading nearly horizontally at the bottom, and dividing as low as possible into 12 to 18 branches, which stand almost straight up without dividing again. Shaping these trees in this manner prevents the branches being weighed on to the ground, and they are less likely to break if they do not divide high up, as there is no abrupt change in thickness. The principal pruning operations take place in the winter while the tree is dormant, but summer pruning is often necessary, especially with the peach. It takes place about the beginning of November, when the tree is growing its strongest. It is with winter pruning that it is intended to deal chiefly, and for an example the apple is selected, as apples are the commonest and most important in this district and the most typical, owing to climatic conditions. The stem.—The usual height for the stem of any fruit tree is a foot to 18in., but this is increased in places liable to late frosts. The only advantage of a long stem is to get the tree out of the reach of frost. The shorter stemmed tree is stronger against wind, more easily got at to prune and pick the fruit, and shades the ground more thoroughly near the stem. When planted out in the orchard a young tree is either cut back to a whipstick of, say, 15in high, or if it is big and well supplied with roots it is treated in the same manner as an established tree When planting out, the root system is greatly reduced by the digging up, and the top should therefore be cut back hard in order to preserve a balance. After the first year's growth in the orchard three shoots should be left, if they are nicely spaced and spread. Cut these above buds facing outwards and close under the bud above. This causes the resulting shoots to stand well out. The second year, with average growth these shoots can be cut to side buds, with a view to dividing into six main branches the following year. After that, as the tree increases in size, the branches can be again divided and subdivided according to available space. The branches can be allowed to take a more upward direction. During the young stages of the apple tree, and, in fact all trees, a great deal can be done in the growing period towards keeping the growth even, by nipping out the tip—only the bud—of those shoots which are growing too far ahead. With young trees it is a common mistake to be too particular about keeping the middle open Growth in the centre greatly assists in spreading the outer branches, but it should not be allowed to become too vigorous. If, through difficulties in shaping a young tree, a branch has remained in the centre until the tree is three or four years old, do not cut it all out at once, but cut it back harder and harder each year, preventing it from growing thicker, and allowing the other branches to develop until the relative size of the scar is much smaller. We now have our three-year-old tree with six main branches spread evenly all round, and probably growing strongly, therefore with strong shoots all over it. The leading shoots should be chosen to continue the main branches, all these leaders being cut as near the same level as possible, and fairly long. The rest of the strong shoots should be cut out or shortened to an inch or so, according to how they are spaced. Any fruit spurs, that is the short wrinkly growths with the large fruit buds on them, are probably better left as they are. Fruit shoots, as they are called, the slender shoots about a foot long with fruit buds on the end and usually standing out horizontally, can be left whole. If they bear any fruit on the end they will be weighed down and will send out short spurs at the bend. If not left whole they should be shortened considerably. No strong shoot should be left in the middle or low down unless it is intended to fill up a gap in the formation of the tree. If the tree is shapely at this age the pruning in after years is easy. The only art is to judge how much to cut out, and how long and how wide apart to leave the leaders. A strong-growing tree often needs scarcely any cutting, but a weaker one needs to have the fruit wood thinned out to prevent it over bearing itself. Keep the fruit as close to the thick branches as is reasonable, then the amount of fruit blown off by gales is minimised. Trees are apt to get broken by a stray cow, or a branch gets caught by the plough tackle. Under these conditions it is difficult to give definite advice, but we must patiently set to work to fill up the gap in time, by selecting a leader, running it up quickly and allowing it to bear little or no fruit till it is up to the general height of the tree and strong enough to carry the crop without being permanently bent too low. This district is well suited to apple-growing, and consequently the pruning is easy if the site is good. No matter how the tree is pruned it will bear some apples at all events. The Pear.—It will be remembered that the branches of the pear should stand more upright than those of the apple, and that they are nearly level at the bottoms, bending suddenly upwards. To get the young tree to spread well, the best way is to leave all or almost all the shoots on the one-year-old tree, simply shearing it, that is, cutting all the shoots to the same level and fairly short. The result should be a thick, round bush, not open in the middle. The second year the tree may be treated similarly, but probably the middle can be thinned out a little, and, of course, any crossing branches must be cut out, and also any shoots that lean towards the opposite side of the tree. By the third year the tree should be able to have the middle cleared out and the required number of main branches selected. When this is done it has a very sprawly appearance, with the 12 to 18 leaders turned upwards. If it is still not spread enough a little central growth will continue to force it outwards. Do not forget the simple process of nipping out the tips in the growing period. It is most effective, and if only the growing bud is removed from excessively strong shoots it is wonderful how the other shoots catch up, and the weakening effect at the time is practically nothing. This attention will save a great deal of trouble and cutting in the winter and, more important still, it reduces the size and severity of the scars. The yearly pruning of the tree is much the same as that of the apple, except for the difference in the shape of the tree. The treatment of the fruit-bearing wood is almost the same, but the strong shoots on the pear usually have fruit buds near their ends. When selecting a leader any fruit buds should be broken off, otherwise the said leader will be bent right down with the weight of the fruit on its end This tendency of strong shoots to bend over with the weight of fruit is often made use of when pruning a badly-shaped tree. One that has run up too straight from the stem when young and has been spread too high up finally becomes a series of layers of branches, some drooping to the ground and others leaning at different angles, and all slowly drooping lower year after year. Such a tree cannot be remodelled into the standard shape. It will bear just as well, though it is more difficult to plough round and to spray, and the fruit is more liable to be shaken off by wind. When pruning it, some of the lower branches may need shortening to keep them off the ground. The others need thinning out perhaps, and the strong growth at the top can also be thinned out, any crossing wood cut away, and provision made for more of these spreading branches, which are continually drooping lower and lower, and therefore need replacing at the top. When doing this a shoot can be developed into a sturdy branch by breaking off the fruit buds, but unless it is kept upright it will soon begin to droop permanently when it bears crops of fruit. Trees of this type are common in private gardens, and are not unsatisfactory. The Peach.—The formation of the peach tree is like that of the apple, except that the fruit-bearing wood being longer it is necessary to have the main branches wider apart. The bud formation is different. The apple and pear have their fruit buds large and distinct, and the wood buds are very small and often by themselves. The peach, and in fact all stone fruits, seldom have wood buds on a young shoot that has not a flower bud on each side. The fruit bud of the apple and pear grows a short spur of wood with a bunch of flowers on the end. The flower bud of the stone fruits is actually a flower bud and opens directly into a flower. The tree is shaped like the apple and the fruit is borne on the short lateral growth, which each year needs cutting back and thinning out according to the vigor of the tree, and, of course, any dead bits removed. The chief art is to keep the growth close to the main branches. The apricot is shaped a little more upright than the peach, and is pruned almost exactly the same, but the main branches may be closer together. Smooth-barked wood on the apricot that is three or four years old will send out shoots, if all beyond is cut off, which is by no means the case with other fruit trees. This is useful in renovating an old tree. The plum is shaped like the pear, but otherwise the pruning is a close repetition of the apricot. The almond is also shaped like the pear and its bud formation is very like that of the peach. Almond trees are often shaped and then left almost unpruned with satisfactory results if the climate is suitable. The chief difficulty with the cultivation of almonds is that they are not easily suited with the right soil and climate, and often the whole crop is destroyed by wind or cold weather. The cherry is another tree that is seriously affected by climatic and soil conditions. It is shaped on the upright model and treated much the same as the almond. It is very subject to rot, and therefore it is wise to avoid cutting as much as possible, and dress all scars with something to keep out the wet. The quince is pruned similarly to the plum, if pruned at all. It is a ready bearer and only needs to be kept healthy. As it is troubled very little by blights, pruning is seldom carried out at all unless it is to allow the fruit to be picked more easily. Tools.—A thoroughly sharp knife is a good tool to use among very young trees, as it does not bruise the bark; a blunt knife is very bad. Knives are slow, however, and for ordinary work shears or snips are used. If kept sharp they do very little damage to the tree, provided they are used properly. The curved pruning saw is for removing the larger branches. The scars resulting should be smoothed round the edges with a sharp knife, to remove the bruised part. No piece should be left jutting out far, and the scar should be kept as small as possible. A large scar should be smothered over with something to keep out the wet and germ life, and thus prevent rot. The best dressings for this purpose are as follows:—(1) Common lead paint, preferably white; (2) grafting wax; (3) thick Bordeaux mixture, *i.e.*, bluestone and lime spray; (4) Stockholm tar. The paint, the Bordeaux mixture, and the tar possess antiseptic qualities and are all good and effective. Grafting wax has the disadvantage of being expensive. Stockholm tar, though last on the list, is always at hand, and is therefore probably the best after all, as it can be put on as soon as the cut is made. A dressing of this sort is most necessary with the cherry tree. If one side or a branch of a tree is allowed to stand higher than another the tree will become more and more lopsided and the desired shape will be lost. If a low branch is prevented from bearing much fruit, and the lateral growth is kept short, it will soon make sufficient growth to regain the balance of the tree, unless it is seriously damaged by rot, breakage, or sunburn. The loss of a little fruit for one or two years on this part of the tree is soon amply repaid when the tree again becomes even and shapely. It is good economy to look upon the bearing of fruit as a secondary consideration during the first four or five years after the trees are planted. Shape the young trees well, and the cost of keeping the orchard will be at a minimum for the rest of the life of the trees. There are no hard and fast rules for pruning, but I have endeavored to show the ideals to aim at, and the principles to follow in order to attain them. All this, however, is worth little compared with commonsense and experience." Mr. C. Beaumont recommended Rome Beauty, London Pippin, Cleopatra, and Dunn's Seedling apples. March was the best month in which to plant orange trees in this district, the roots would then be well established before the winter. A piece of bagging should be put on the east and over the top of the young orange trees, to prevent the sun shining on them whilst the frost was on them. They should only be pruned sufficiently to allow of the light gaining access to all parts, and to facilitate spraying. These trees would do well in properly drained soil, even if a heavy rainfall was experienced. Drainage was best done by using a 4in. pipe. It was a good plan to go through a heavy subsoil with a subsoiling plough. This district was a good one for fruit-growing.

Inman Valley, July 16.

(Average annual rainfall, 26in. to 27in.)

Present.—Messrs. H. J. Meyer (chair), H. J. Jagger, H. G. Allert, R. A. Mayfield, V. J. Tugwell, R. J. and H. T. Martin, L. V. Hurrell, M. J. Meyer, A. McCoy, F. J. and J. G. Barratt, H. M. Parsons (Hon. Sec.), and three visitors.

Potato-Growing.—A paper on this subject was contributed by Mr. Tugwell. The swamp lands, he said, should first have a main drain to carry off surplus water, and this should be large enough to cope with floods, or serious damage to crops might result. He would commence to clear at the low end and work up, to facilitate putting the inside drains in the best places. He would dig in July or August, so that the soil would be sweetened for October and November planting. Sandy soil should be ploughed early with the first rains, and planted with such crops as barley or oats, to be dug in before planting potatoes. Silty soils he would plough early and leave, only working them up if weeds appeared before planting. For the swamps the seed should be grown in sandy soil and should come from the best of the crop. He would select them about the size of a small hen's egg and plant them whole, as cut seed were liable to rot in the swamp. For sandy soil he would select seed from which four sets could be cut. For the silt in the Inman Valley he recommended seed about as large as a hen's egg or a little larger, which could be cut in two to destroy the crown eyes and thus prevent too many tops from growing. *Planting.*—The best returns were secured by digging in the seed. The next best method was to plough the land and then drill in the seed across the furrows. The method least recommended was to plough the seed in. On the swamps, October, November, and December planting gave the best results, the seed being put about its own depth below the surface, from 1ft. 6in. to 2ft. apart, with 2½ft. to 3ft. between the rows. He recommended about half a ton of bonedust or potato manure per acre put in on the seed. On sandy soil the seed could be ploughed in to a depth of 2in. to 3in. and the manure spread broadcast on top. Silty soils, when properly cleared and planted in September to November with 1ft. 6in. between the seeds and 2ft. 6in. between the rows, with half a ton of bonedust or potato manure, stubble or cattle dung, either spread on top or in the furrows, yielded well. The crop should be hoed at least twice on the sandy and silty soils. On the swamps there was usually enough top growth to shelter the crop. He preferred sprinklers for irrigating. Digging out the tubers was most easily accomplished by using a five-tine fork, but ploughing was a quicker method, if not the cleanest, of getting up the crop. When picking up, the best seed from the best plants should be saved and the inferior tubers sold. *Varieties.*—For the swamp lands—Carmens, Redskins, Up-to-Dates, Prolifics, and Snowflakes, the last-named being particularly well able to stand the wet and yielded a heavy crop with six month's growth. The others would grow in about four months. For sand—Carmens, Up-to-Date, Bismarck, and Redskins, planted in January and February for early crops. Any of these varieties would do well on the silt with irrigation. The use of pig manure would encourage scab. Finally, he said, that with water and manure potatoes could be grown in any soil. Good discussion followed. In reply to questions, Mr. Tugwell said he picked out the potatoes after digging that were running wild. Flooding the potatoes while the tops were green, to kill the grubs, would not injure the growing tubers if done quickly and quickly drained. Mr. Jagger preferred to pull up all roots of plants that had a tendency to run wild while they were growing if it was intended to secure seed from that plot. Mr. Allert recommended a trial of sulphate of potash for potatoes.

Farm Improvements.—Mr. H. J. Jagger read a paper on this subject. He would confine himself to one or two lines of farm improvements, he said. Most farmers in this district were being faced with the fence problem. A stock fence on the clear land on the Bald Hills was not suitable on scrub country that was subject to fire. If obtainable, he preferred split posts of pink gum, from trees that would split two or four or even more to the length. If pink gum was not easily obtained, red or blue gum made good posts.

The trees selected should be neither too old nor too young. The posts should be about 5ft. 8in. or 5ft. 9in. long, and not less than 5in. by 4in. at the small end. The strainers should not be less than 1ft. at the small end and 7ft. long for the end or corner posts, and 6ft. 8in. for use in the middle of the fence. These, together with struts or stays about 15ft. long and not less than 4in. at small end, should be placed on the line in the dry weather when the hard ground facilitated carting. The erecting should be done when the ground was thoroughly wet and soft, and the holes were easily sunk. It was important to have the sight sticks firmly and correctly placed in a straight line. Pieces of ½in. or ¾in. gas piping, 6ft. or longer, served the purpose excellently, if a piece of iron sharpened to a point was driven into one end, and the other painted white. For ordinary purposes a fence 3ft. 6in. high, with the posts 3ft. 8in. above ground, was all that was needed. Barbed wire he did not like, for it was dangerous to stock if slack. Seven wires made a better fence than six, and No. 6 wire was preferable to Nos. 8 or 10. For ordinary fences, where cost had to be kept down, six wires were enough, the top being No. 6 and the others of No. 8 galvanized wire. If no cattle or horses were likely to run in the paddock six wires of No. 8 would suffice. The posts should be 8ft. apart or eight to the chain. The strainers not less than 5 chains apart, and if the ground was fairly level 7 or 8 chains between was not too long a distance. To bore the posts he would use a ⅝in. bit, making the bottom hole not more than 5½in. above ground. The next three spaces each 6in., with 8in. between the fourth and fifth wires, and 10½in. between the top two. If new wire were used a spinning jenny was useful. The strainers should be securely rammed and firmly strutted, especially at the ends and corners. Strain the top wire right through the whole length of the fence before straining the others, to guard against the possibility of the centre strainers moving. Then work downwards. New wire should be stretched by treading it during the straining. For a fence subject to scrub fires, wooden posts should be placed farther apart, say 42ft., with one tee iron post between and two flat iron posts between the tees and the wooden ones. It was best to bore alternate strainers only, as the draught through the auger holes, in case of fire, caused the strainers to burn. The wires could be put round the others and stapled in position. All scrub, etc., that would help to destroy the fence in case of a bush fire should be removed. *Buildings.*—No hard and fast rules could be laid down in regard to these, but in all cases they should be substantial. Buildings erected as a makeshift often had to do service as long as they would hold together, and were often unsightly and inconvenient. It was wise to plan out the proposed building, drawing a rough sketch, and taking note of future requirements. When putting up a stable one should keep in view the probability of needing a chaff house in a suitable and adjacent position. Farm buildings dotted down without any method looked bad and were not convenient. If stone was easily obtainable this should be used for farm buildings. Almost any handy man could do his own mason work. If lime was scarce, pug could be used and the surface flushed and pointed up with mortar. In the absence of stone, galvanized iron was the next best material. Waste timber and split slabs might be used for sides, but iron was best for the roof. Members agreed that the height suggested in the paper was sufficient for all quiet stock. Emphasis, however, was laid on the need for very thorough strutting. Resisteel was said to be a good material, which did not get slack so quickly as iron wire, but it should not be bent too short round strainer posts or drawn too tight. Mr. Hurrell thought iron too cold for stable roofing. He preferred to thatch. Others thought that the danger of fire and need for periodical repairs rendered thatch unsuitable for this purpose.

Kanmantoo, June 14.

(Average annual rainfall, 17·90in.)

PRESENT.—Messrs. A. W. Hay (chair), W. Shepherd, W. Johncock, R. Downing, R. Critchley, J. Mills, J. Critchley, H. Downing, S. Downing, H. Shepherd, W. Mills (Hon. Sec.), and one visitor.

WOOL.—Mr. J. Mills contributed a paper, in which he said that different types and qualities of wool were yielded by different sheep, and these had to be separated before the raw material could be made use of. For classing, a rolling table about 10ft. by 4ft. 6in. and piece-packing tables about the same size and in numbers according to the quantity to be handled, were necessary. A classing table capable of carrying a dozen fleeces was required, and the tops of all should be so constructed that the backs and second cuts would fall through. The fleece should be taken from the shearer by each breech, the rest of the fleece being gathered towards the body and then thrown on the rolling table so that the outside edges just fell to the edge of the table. Skirting should commence from behind the shoulder, working towards the head, taking off all burrs, sweaty pieces, and daggs, together with any remaining belly and britch wool. Both outside edges should then be turned in, and the fleece rolled from the britch to the shoulder. Pieces and bellies should be treated similarly, but if the clip were small the latter should be skirted lightly, and the skirtings from each could be mixed. Small clips should not be classed into more than two lots, but in any case all strong and tender pieces should be kept out, as one of these found in a bale by the buyer would result in a lower price for the lot. Placing the wool in bins before baling would enable the classer to detect any mistakes that might have been made. The branding on the bales should include the name of the station, the class of the wool, with the sex of the sheep, and then the number. This should be placed on one side running with the cap of the bale, and on the top, which would obviate trouble in picking out. Mr. Hay thought two lots of fleeces, with the extra strong, fatty, and broken fleeces taken out, was sufficient for the small grower. He would not take out the tender (as distinct from broken) wool, but would put it in the second class. The Hon. Secretary thought that if the bulk were sound, it would pay to keep the tender wool, *i.e.*, that which would break easily between the fingers, by itself. Broken wool should certainly come out.

Meadows, July 14.

(Average annual rainfall, 35·52in.)

PRESENT.—Messrs. G. Ellis (chair), G. T. Griggs, H. A. Kleemann, W. J. Stone, F. Nottage, H. Thorn, A. L. Ellis, F. W. Vickery, E. W. Vickery, J. Stone, W. H. Bertram (Hon. Sec.), and two visitors.

FATTENING SHEEP AND LAMBS IN THE HILLS.—The Hon. Secretary read the following paper on this subject:—" In a district like this, especially on the better class of land, no farmer should sell his sheep or lambs for stores unless for breeding purposes, because if sold as stores the man who buys and fattens is in most cases the man who makes the profit. Care should be taken never to overstock. It will pay well to have plenty of feed, as sheep grow much larger and faster, and when put in the fattening or topping-off paddock do not take nearly so long to be ready for market. The farm should be fenced into convenient sized paddocks. I would advise farmers in this district to direct their attention more to the cultivation of field peas for topping off sheep and lambs. It is very necessary to have a good supply of water in the paddock, as peas are very heating, especially in the summer months when ready for feeding off. Nearly all our rough land, when cleared, will grow peas, and you will agree that it will be only by means of cultivation that we will be able to make good grazing paddocks. The natural grasses in the Hills districts are very poor for fattening purposes; in fact, my experience has been that taking this district on a whole it is even very poor store country for stock on its natural grasses excepting during October and November. One of the chief drawbacks is a deficiency in salt. Growing peas for grazing purposes not only improves the paddocks by means of cultivation, but ought to be turned into a good paying proposition from the first year if grazed off with fat stock, to be put on the market labelled prime quality. If we do not breed sufficient lambs on the farm, there is generally a good opportunity of buying well-grown fat lambs in December, when the natural spring grasses are done. Your pea paddocks will thus top them off during the months of January, February, and March, when feed is scarce in other parts of the State, and you can generally rely on a first-class market for prime quality stuff from March right through the winter months. In a district like this, where we can only keep a limited number of sheep, it will pay us to put them on the market in a prime condition, as there is always a keen demand for prime quality, whereas what we call fats are not so keenly competed for by the trade." Discussion—The Chairman considered that an acre of fair average peas would top off from 20 to 25 lambs. Peas made the meat a yellowish color, and butchers always preferred lambs topped up on this crop for prime quality. Members generally considered that a crop of peas was one of the best fodders for topping off lambs and sheep.

ANNUAL REPORT.—The Hon. Secretary reported that 11 meetings had been held, with an average attendance of 11·5. Good practical subjects had been discussed at every meeting, and during the year the Conference of Hills Branches had been held under arrangement with this Branch. The Hon. Secretary said that there was need of a larger membership of producers who were willing to give their knowledge to others. He urged fellow members to take up the work of the coming year with energy and enthusiasm.

Meningie, July 19.

(Average annual rainfall, 18·87in.)

PRESENT.—Messrs. W. Tregilgas (chair), Ayres, Hiscock, Scott, Deane, Newson, Hastings, Mincham, Martin, Williams, and Wright (Hon. Sec.).

DRENCHING STOCK.—Mr. R. M. Scott read the following paper :—"It is very necessary for persons that own stock to know how and be able to give medicine, both in the form of drenches and balls. Many a dose of medicine, of the utmost value to the animal, is lost through not knowing how to administer it properly. Small doses of liquid are best given to the animal with a syringe. With a horse, stand in front of the patient, fill a syringe (one that can be worked with one hand is absolutely necessary), open the mouth with the left hand by inserting it through the mouth and holding the fingers up on edge, pass the syringe between the fingers, and shoot away ; withdraw the syringe and elevate the head a little with the left hand. So continue till the dose is all down. When properly done, not a drop is wasted and the horse is not excited. With large doses a bottle must be resorted to. Pass a loop in the mouth of the horse to catch the upper jaw, then raise the head a little by running the line over a pulley. No animal can swallow with the head too high. Stand on the right side of the patient and pour the medicine very slowly, never use any violence to make the horse swallow, let it have its own time. Should the animal cough, strangle, or choke, let the head down immediately. It does not matter if the medicine is lost. It is better to lose the medicine than the animal. Medicine may be given to a horse by what is known as a ball. Make the ball about the size of a man's big finger. Stand in front of the animal, and take a firm hold of the tongue with the left hand. Draw it down between the front teeth, but never draw it to one side. Take the ball between the fingers, the thumb being drawn into the palm of the hand. Then pass it back, placing it on the root of the tongue, and as you let it go give it a little push with one of the fingers. Take the hand out of the mouth and let the tongue go, and close the mouth and lift the head a little. If you then watch on the left side of the neck you will be able to see if the patient has swallowed his medicine. Even in this operation be sure not to abuse or excite the animal, but let it have its own time. A pig cannot take a drench properly if you hold him on his back—his head must be rather down than up—and the same applies to cattle. Dogs must have their teeth almost closed before they can take anything down the throat. Many a good dog has been killed through holding its mouth open when trying to give it a dose of medicine."

ANNUAL REPORT.—The Hon. Secretary reported that 12 meetings had been held during the year, with an average attendance of nine. The average number of meetings attended by members was 4·1. There were now 15 on the roll. Five papers had been read and one homestead meeting held. He appealed to members to put more energy into the work of the Branch, and before the meeting closed an excellent programme of subjects for the ensuing 12 months was adopted.

Morphett Vale, July 15.

(Average annual rainfall, 23·32in.)

PRESENT.—Messrs. L. F. Christie (chair), H. O'Sullivan, H. V. Sprigg, J. Perry, A. Anderson, F. Rosenburg, T. Higgins, and E. E. Hunt (Hon. Sec.).

SHOEING HORSES.—Mr. Christie read a paper on this subject, in which he said—Under ordinary circumstances the colt should have a sound, perfectly formed foot, with very little excess of horn, the front nearly round, the hind slightly oblong. If the surface is uneven level it down with the rasp. Then select the shoe, which will require to be heated. First form the toeclips, which should be short and strong, and not a great triangular projection reaching half way to the coronet, and which, when hammered in at the point, causes a pressure on the sensitive interior, and often lameness. While the shoe is hot shape it to fit the foot. Apply it to the surface when hot. This will indicate any unevenness. Rasp or pare the hoof until the shoe has an even bed. When fitting the shoe burn the hoof but slightly, as this is ruinous to the horn. Keep the shoe wide at the heels, well outside the walls, and clear of the frog. Do not touch the sole, frog, or bars, as nature has provided them for protection, and the old style of paring them away should not be permitted. After fitting the shoe to an even bearing, place it on the anvil and with the hammer spring the heels about $\frac{1}{16}$ of an inch, or less, so that when nailed on the foot there will be no bearing on the heels. This is a very necessary precaution with horses that have weak heels or quarters. For a light horse six nails are sufficient. They should be well towards the toe on account of the expansion and contraction of the heels when the horse is in motion. Never drive the nails too high up, but give them a short, firm hold. A good deal depends on the thickness of the walls, and horses vary considerably in this respect; therefore discretion must be used. I have often known horses go very lame after shoeing, and have found that though they had not been pricked, the nails had been driven so near the quick that they must have caused intense pain. If a horse flinches when a nail is driven it should be withdrawn at once; if pricked there will be a slight bleeding, but seldom any after effects. It is a good plan to pour a little carbolic and oil, or tar, in the hole. The clinches should be short. Make a slight mark underneath with the edge of the rasp, which will allow them to fit in neatly and strongly. After clinching the nail there will be a little horn at the toe that should be rasped off, but on no account use the rasp above the nails. It is a common practice with shoeing smiths to rasp and polish the hoof right up to the coronet, but beware of the man who does this. Nature has provided a beautiful varnish for the protection of the outside walls which, if removed by the rasp, exposes the horn and causes it to crack and lose its elasticity. It is a most injurious practice, which should never be permitted. There is no objection to neatness, which can be attained by close attention to finishing and fitting the shoe and clinching carefully. The first principle in shoeing is protection. I advise all amateurs to acquire a good knowledge of the anatomy of the horse's foot. Always remember that it is not a block of wood, but a most delicate and wonderfully constructed member. A shoe should not be allowed to remain on more than six weeks. If left too long it is apt to cause contraction, corns, and other troubles. Cutting out the sole bars and frog is another cause of contraction, &c. Always shorten the foot from below and not from the front. Leave the heels of the shoe as long as possible, but discretion must be used where a horse over-reaches. Members agreed that the paper contained information of considerable value, especially in regard to the springing of the heels of the shoes, which they considered was most essential.

Mount Barker, July 16.

(Average annual ranifall, 30·93in.)

Present.—Messrs. H. N. Bell (chair), F. H. Adams, A. B. Blades, S. J. Bishop, J. Choat, C. Crompton, J. and G. Cleggett, J. F. Moore, J. Morris, D. Monfries, B. and J. Pope, B. and W. T. Stevenson, T. Simper, J. Frame, A. Ferguson, L. Hughes, H. Jones, J. Little, A. Liebing, J Thomas, J Wilks, E. P. Mappley, C. G. Brendler, J. E. Smith (Hon. Sec.), and one visitor.

Criticism of Address by Director of Agriculture.—Discussion took place concerning Professor Lowrie's address at the previous meeting.

Lime.—Mr. J. Frame had found considerable benefit resulted by applying 3 tons of lime to one and a half acres of lucerne Mr. J. G. Thomas believed with Professor Lowrie that lime was very much needed in the Hills districts. Some years ago it was used round the township, but it was very much cheaper then. He thought that farmers might co-operate with advantage. Mr. Pope had tried lime and shells on peas, and the result was so marked that a farmer who was driving past called in to ask what they were using. They intended to go in for experiments on a larger scale. Mr. B. Stephenson said the local lime was far superior to that from the Peninsula, and they could therefore do with less of it. Mr. Jones advised running it through the drill by itself the year after peas had been grown on the land, but Mr. Pope thought they would get better results by putting it in with the pea crop. He also thought better results would be obtained by evenly distributing the lime instead of putting it in furrows.

Manures.—Mr. Frame considered bonedust one of the best manures for the district. Super. had not given much satisfaction with hay or pea crops. Thomas' phosphate he had used with good results. He drilled the bonedust in with the wheat. Mr. Pope thought that bonedust would not pay on a cereal crop only, but might if used for a rotation.

Drainage.—To cope with surplus water Mr. Frame recommended ploughing up and down hill, but Mr. Pope considered that this would lead to loss of soil, which could be ill afforded.

Wheat.—Mr. Frame spoke highly of Comeback for grain, hay, and chaff. For hay he also recommended Bobs and Crossbred 53, but the latter did not come away very quickly. Mr. Pope favored late wheats. Comeback he considered good for show and for its flour, but that was all. He favored Crossbred 53, Correll's No. 7, and Leak's Rustproof. Mr. B. Stevenson liked King's Early. With him it had done better than Leak's Rustproof. Golden Drop had yielded him 2½ tons to the acre. Mr. Jones avoided bearded wheats because of injury to horses' mouths Bobs he liked for hay and chaff;

Le Huguenot also did well. Mr. A. B. Blade and Mr. Simper spoke highly of White Tuscan. Opinions were divided as to whether White Tuscan would be badly affected by rust Messrs. Frame and Pope were emphatic in the opinion that the agriculture of the district generally was of a much higher standard than that of years ago.

Port Elliot, June 21.

(Average annual rainfall, 20·33in.)

PRESENT.—Messrs. J. Brown (chair), J. Chibnall, D. J. Gordon, W. Squires, H. Green, J. McLeod, G. J. Snell, and W. E. Hargreaves (Hon. Sec.).

IRRIGATION.—Mr. J. Brown, who for 30 years had made a practice of irrigating on a small scale, read a paper. Small areas of from one acre to 20 acres intended for irrigation, should be graded to a fall of about 6in. in one chain, the water being flooded on to the land by means of pipes. The selection of the pumping plant was a matter that required very careful consideration. The size of the piping in relation to the pump was a subject on which there was considerable difference of opinion. He thought nothing less than a 4in. pipe was necessary for a 3in. pump. In reply to questions, he said that for potatoes he generally distributed about 8in. of water in four waterings, the last being three or four weeks before the tops died down. He worked the land about four times with the horse hoe whilst the crop was growing, the last hoeing being done just before the tops closed over the spaces between the rows.

PEAS.—Mr. J. McLeod reported having used 2cwts. of lime to the square chain on peas, but there was no apparent improvement in the crop. A white pea crop sown by Mr. Chibnall had been completely destroyed by magpies.

Uraidla and Summertown, July 7.

(Average annual rainfall, 44·35in.)

PRESENT.—Messrs. H. F. Johnson (chair), S. and E. Hawke, J. Rowe, H. G. Dyer, E. Hart, G. Collett, F. H. Stacey, W. Kessell, G. Prentice (Hon. Sec.), and one visitor.

GARDENERS' SUPPLEMENTARY TOOLS AND APPLIANCES.—Mr. H. G. Dyer read a paper in which he said that every gardener should have a small portable forge to effect minor repairs, and a good vice in addition to a supply of wood working tools, such as hand saw, draw knife, chisels, plane, square, brace and bits. Iron or steel heated for sharpening should be made almost white hot, but must not be allowed to burn. When tempering, the point should be dipped into water for a second or two and then withdrawn until the blue color was seen to approach the point. At that instant it should be cooled right off.

Woodside, June 18.

(Average annual rainfall, 31·95in.)

PRESENT.—Messrs. P. Keddie (chair), F. Baldock, W. King, H. Rollbusch, G. J. Sampson, J. Keen, C. W. Fowler, J. Morcom (Hon. Sec.).

FARMYARD MANURE.—In a short paper on this subject Mr. Disher recommended farmers to heap farmyard manure on the site of an old stack or pea threshing floor. The heap should be commenced small, being gradually increased in size until a height of 6ft. had been attained, when it should be raked in until it was raised to about 10ft. in height at the top. Cleanings from the pigsties placed around the bottom would effectively keep the fowls from scratching at the heap. The manure should not be left in heaps in the paddocks (this would probably result in rank growth), but should be spread immediately. The acid contents were then evenly distributed over and washed into the ground with the first rains. Land intended for potatoes should be manured and ploughed some time before being planted, a good plan being to sow peas with the manure and plough the crop under before putting in the potatoes.

SOUTH-EAST DISTRICT.

Frances, July 12.

(Average annual rainfall, 20·74in.)

PRESENT.—Messrs. McGillivray (chairman), Tompkins, Baldock, Holmes, Pfitzner, Cooper, and Feineler (Hon. Sec.).

PRICE OF CORNSACKS.—Mr. Pfitzner considered that the price asked for cornsacks was extortionate. The price had gone up from about 4s. to 8s. during the past few years, and though adverse seasons had been reported in India, if an official inquiry were made he thought failure of production might not be the greatest cause of the rise. All present favored an official inquiry.

GRASSING PADDOCKS AFTER CROPPING SEVERAL YEARS.—It was reported that paddocks cropped for several years, when left out, had very poor crops of grass, excepting silver grass, which grew abundantly. The Chairman stated that a neighbor of his had seeded, last year, English rye grass with his cereal crop, resulting in a splendidly grassed paddock after the crop had been stripped. The season was very favorable for grass crops last year. Mr. Cooper stated that paspalum grew well in sandy and light soils, but as it was so succulent the sheep ate it down too hard, and it could not make much growth. The Hon. Secretary had a paddock of Italian rye grass which supplied a great deal more feed than the paddocks of natural grass. It was considered that Italian rye grass, being a biennial, was not so suited for pastures as the English rye grass, which was a permanent grower. The Hon. Secretary had been advised to put in Italian grass as it grew a greater quantity of feed in a shorter time, after two years of feeding to let it go to seed, and work the ground well and put in a cereal crop. The next season would result in a better crop of rye grass, and the cereal crop would not have suffered. He had two plots of rye grass in this year as a test, one of 35 acres put in at rate of 12lbs. to 15lbs. Italian grass and 80lbs. super. to the acre, with 1¾bush. of Algerian oats; both the grass and oats appeared to be growing well. The second plot of 20 acres, seeded with a bushel of wheat, 1cwt. super., and 12lbs. English grass was just coming up. Mr. Pfitzner stated the rye grass did not grow well in heavier soils, as the dry weather cracked the surface and parched the roots.

Glencoe, July 16.

(Average annual rainfall, 33·84in.)

PRESENT.—Messrs. A. Dow (chair), J. Dow, J. and W. Holloway, J. T. Halliday, F. A. Telfer, W. D. Mitchell, and G. F. Ferguson (Hon. Sec.).

PLOUGHS AND PLOUGHING.—Mr. W. D. Mitchell read a paper on this subject. After tracing the development of the plough from the wooden implement of the early days, he said that the present day ploughs could be separated into two types, those which were simply required for breaking up the land for further cultivation, and those which cut a furrow to a required measurement, as was the case with the one used on land for potato-planting. Good ploughing could only be done by laying the area out in proper lands, carefully measured, and struck out as nearly straight as possible. A straight course could not be kept with a plough imperfectly set. Mr. A. Dow preferred short mouldboards, but Mr. Ferguson said these would not turn the furrows in stiff land. Mr. W. D. Mitchell said the Glencoe land was very good for ploughing, but in some of the stiff Mount Gambier soils, which carried a heavy sward of grass, it was necessary to pack the furrows well, or they would turn back, perhaps for a chain or so at a stretch, behind the ploughman. With a double-furrow plough, with a shifting dibber, and cutting a 10-in. furrow, it was possible to treat three acres in a day. Mr. J. Dow thought some types of modern gang ploughs were too light. Mr. F. H. Telfer had done good work in fallow with a three-furrow implement drawn by three horses. Members generally favored three-furrow ploughs for potato-planting, on account of the saving in labor effected. Mr. J. T Halliday preferred the single furrow.

FEEDING-OFF EXPERIMENTS.—Mr. A. Dow referred to the Government experimental plots on his farm, which had been sown with various grains for green feed on March 28th. Towards the end of May he had turned 10 cows on the five acres for 22 days. They ate down the unmanured plots before grazing the others to any extent. Mr. G. Ferguson said the acre plots on his farm had been sown with Algerian oats, Cleveland oats, Cape barley, rye, and Baroota Wonder wheat, and half of the area of each plot had a few pounds of vetches sown with the other seed. The wheat had made the best growth, but he did not notice that the stock showed any preference, except that they did not eat down the rye so bare as the other plots. He had grazed 75 sheep on the plots for 14 days, and since they had been removed all had made rapid growth, except the Cleveland oats, which he did not think would prove suitable for feeding purposes.

Keith, June 21.

(Average annual rainfall, 19·20in.)

Present.—Messrs. J. McIntyre (chair), J. B. Makin, J. A. Lock, W. H. Morcom, F. W. Schultz, W. Fulwood, E. J. Hutchings, E. Leishman, jun. (Hon. Sec.), and one visitor.

Seed Wheat.—Mr. F Packer read a paper in which he emphasized necessity for carefully grading wheat intended for sowing. Every three years it was advisable to procure fresh seed, that from the North, from which he had secured up to 5bush. per acre above returns from locally grown seed, being recommended. Federation, Bluey, Yandilla King, Purple Straw, Lotts, Bunyip, and Gluyas would do well in this district. Some of the varieties mentioned would mix well with Le Huguenot for hay. Farmers should exchange varieties with men in other districts upon whom they could rely for clean seed. Members generally agreed that Federation, Lotts, and Bluey were good varieties for this district. Several had obtained good results from Comeback and Clubhead. Le Huguenot, when sown with oats, made chaff of good quality.

Naracoorte, June 14.

(Average annual rainfall, 22·60in.)

Present.—Messrs. L. Wright (chair), W. H Smith, W. E. Rogers, F. Holmes, A. Caldwell, W. Loller, C. Bray, and S. H. Schinckel (Hon. Sec.).

Rotation of Crops.—In introducing a discussion on this subject, Mr Loller said the South-East was more suitable than the North for a system of rotation of crops, and continuous cropping, on account of the heavy rainfall. When dealing with new land that was somewhat sour, he would first sow it with oats in March or April. The working it received in connection with this crop would fit it for a wheat crop to follow. Barley could then be put in as a third crop, and rye could follow. The weeds germinated early, especially if the land were lightly skimmed, and they could be fed off with sheep. The rye crop should be followed by peas, which would raise the nitrogen content of the soil. This rotation had been very satisfactory on his land, and he believed the continuous cultivation would go a long way in the eradication of sorrel The Chairman had always found that oats did better following wheat. If the land were very stiff he might sow oats first and cut the crop very green for hay. If that was not done the wheat crop following would be dirty. With modern implements it should be possible to get a good seed bed for wheat, even in new land. He advised a crop of wheat and then oats, and after the land had been left out, a fodder crop, such as turnips. Five or six grain crops in succession would probably leave the land sick. It would become very dirty, and sorrel would be troublesome. After root crops he would leave the land under grass for a year or two. Land in Penola had been cropped 13 times in succession with oats, no manure being used, and the last crop was a good one, but the owner always took care to cut the hay green. It was the ripening of crops that exhausted the soil. He believed in growing a number of oat crops in succession on the strong black soil, such as that in the Bool Lagoon country. Mr. W E. Rogers thought it unwise to grow more than three grain crops in succession. After grain he would put in root crops or peas, which would replace to some extent constituents taken out of it by the grain crops. Mr. Bray said oats on new ground did better than wheat. The best time to deal with sorrel was in January and February. If a man sowed 100 acres with rye he would very likely find a lot of it on his hands. He raised 20 or 30 bags a year, and had as much as he could do to get rid of it. Wheat and oats were always saleable. Mr F. A. Holmes agreed that as a general rule oats should follow wheat. Cutting oats green for hay was a great point in maintaining the fertility of the land. Mr. Smith thought there would be difficulty in getting rid of a crop of rye, but peas would sell readily. Successive crops of oats would check sorrel. He had grown peas and maize, and had obtained good crops of oats and wheat after peas Mr. Schinckel said grain crops exhausted the land of potash, and this constituent had to be returned to the soil. He would sow peas first, and then wheat and oats. There was more money in wheat, and that was the reason farmers stuck to this crop. Kale, rape, sorghum, and maize could with advantage be included in the rotation Wheat following maize did remarkably well. Mr Loller, in reply to criticisms, said his remarks on rotation of crops had more to do with the larger crops for which they had a ready market, and he did not take into consideration sorghum, maize, &c. Farmers did not sow these to any extent. Such crops would not grow as well in the South-East as in the northern portions of the State. They had not the quality of soil in this part, and rich manures were needed for maize and sorghum. He would put in oats first in new land which needed sweetening, as they could be grown on land where wheat would not do well.

Exhibits.—Mr. Loller tabled samples of wheat and rye grown for green feed. The seed had been sown in March with 1cwt. of guano to the acre. The rye had been drilled in, and the wheat cross drilled, and at the time it was cut, during May, it had attained a height of between two and three feet.

Penola, July 5.

(Average annual rainfall, 26·78in.)

Present.—Messrs. H. Richardson (chair), A. H. Strong, A. E. Lampe, D. Adamson, S. L. Norman, J. Redman, D. A. Fullerton, P. H. Kilsby, W. Miller, H. Ricketts, and S. Ockley (Hon. Sec.).

Eradication of Dock.—In reply to a question, Mr. P. H. Kilsby said that the only method to cope successfully with dock was to pull it and burn it. Mr. Fullerton said on hard ground it could be lessened considerably by hoeing, provided all the roots hoed up were burnt and not allowed to lie on the ground.

What to Sow with Rape.—Mr. Adamson said rape alone sown in September did not seem a satisfactory crop for sheep. It needed something else mixed with it. Vetches were recommended by those present.

Breeding Comeback Sheep.—Mr. Fullerton said that to breed Comeback sheep Lincoln rams should be used on Merino ewes, the progeny being known as first cross. On the first cross ewes use a Merino ram and the resultant flock would be Comebacks. They were usually good doers, and besides cutting a valuable fleece of wool, though light, they afforded an excellent carcass when fattened. Great care should be exercised when the Merino ewes were lambing to the Lincoln rams, as the lambs generally possessed the large head typical of Lincolns. He would never use aged maiden ewes for this purpose, because this would result in great mortality among the ewes. Four-tooth ewes were the best, as they apparently were not so set in the bone as the older ones. If Romney Marsh rams were used instead of Lincolns, the trouble at lambing was minimised, and the lambs obtained would mature more quickly, although when full-grown sheep the cross from the Lincoln might be larger. First cross ewes were without doubt the best mothers, as they possessed more milk than Merinos, and consequently were not so apt to desert the lamb. One line of Merino ewes he had were so bad that he was obliged to build a brush yard in which to put many of the ewes, and kept them there until they took to their own lambs. It was much better if a fairly small enclosure were available to put such ewes in. When helping a strong ewe to lamb, it was a mistake to pull the lamb right away, because being strong the ewe was apt to get up at once and run away. After the head and shoulders were free the ewe should be left. She would have no trouble in completing parturition. It was fatal to assist a ewe unless she was straining. When a ewe showed signs of weakness and experienced a difficulty in rising, it was wise to wait till she had lambed, and then help her to her feet and walk her about till she was able to go unaided. If Merino rams were used on Lincoln ewes to obtain the first cross the progeny did not seem to have the same uniformity as the universal method advised. Mr. Adamson had often slung weak ewes up to a wire fence to allow the lamb to obtain nourishment and the ewe to regain the use of her cramped limbs.

Tape Worm in Lambs.—Mr. Fullerton thought that a change of pasture was the only remedy for this complaint. A local sheep station had a large number of lambs afflicted with tape worm. They were turned into a paddock of freshly-burnt scrub, and in a few weeks the change was marvellous and the flock completely recovered.

Tintinara, June 28.

(Average annual rainfall, 18·78in.)

Present.—Messrs Donaldson (chair), C. M. Ives, Scott (two), Bell (three), Koeppen Wendt, Northcott, Stead, D. T. Kennedy, J Helling, Henderson (two), Bainger, C. P. Hodge, M. F. Hodge (Hon. Sec.).

Fallowing.—The following paper was read by Mr. D. Bell: "New land intended for fallowing should be logged between November and January. A suitable log for this work is one 18ft. or 20ft. in length and about 18in. in diameter. This can be worked comfortably with six horses and two drivers, and should break 35 acres a day in light mallee or heath country. To ensure a clean burn the mallee land sould be gone over twice, but with the heath I hardly think this necessary. I consider February the best month in which to burn off. If left later rain may prevent a clean burn. Experience has convinced us, as well as others in this district, that a fire break is necessary. To prepare this, cultivate very lightly a strip 12ft. in width, then rake it with an ordinary horse rake. This will make a clean break when ploughed. Ploughing should be started immediately after seeding is completed, not later than the middle of June. In heath country plough to a depth of 8in., and so drag out most of the yaccas. The next working should be done with a disc cultivator or harrows about the end of August or the beginning of September. The disc harrow is preferable to the ordinary harrows for this class of land, on account of the fibrous state of the ground. Another working with the same implement before harvest is necessary. In mallee land ploughing to a depth of 5in. is sufficient. It will pay better to grub the yaccas, which are few on this land as compared with the heath, than to plough to a greater depth. Harrow twice directly ploughing is finished, and cultivate before harvest with a disc cultivator. For fallowing old heath land I prefer the disc cultivator, turning the land to a depth of 4in. being all that is necessary. The following working should take place not later than the middle of August to a depth of 2½in. This can be done with a disc harrow or skim plough. If any weeds are cut during the second working the harrows should follow immediately after. Should rain fall during the summer months the opportunity of getting the team to work on the fallow should not be missed. Dry working, in my opinion, is a great mistake, unless on ground intended for summer fallowing, *i.e.*, land ploughed between harvest and seeding, and left until the following year before being cropped. By adopting this method more land can be put under fallow each season. When practised on dirty land, all weeds start with the first rains and can be killed during the winter and spring months while the ground is wet."

Shipping Wheat, Wallaroo.

AGRICULTURAL PUBLICATIONS.

The following publications have been issued by the Department, and are available for distribution at prices mentioned:—

Vinegrowers' Manual, by A. Sutherland, 6d.; posted, 7d.

Reports of Conferences of Australasian Fruitgrowers held at Brisbane and Wellington, 1s. each, or 1s. 1d. if posted.

Journal of Department of Agriculture of South Australia, 1s. per annum in advance; 3d. per single copy to residents of South Australia; 2s. 6d. per annum to other places.

Any of the following Bulletins and Leaflets may be obtained by sending a penny stamp for postage:—

Agriculture, Miscellaneous: Agricultural Bureau Congress Reports; Agricultural Experiments; Amount of Spirits to be Extracted from a Ton of Raisins; Depth of Sowing of some Agricultural Seeds; Housebuilding in New Districts; Lucerne Cultivation and Management; Milling Experiments; Reclamation of Land; Roseworthy College Farm Flocks; Roseworthy College Harvest Reports; Roseworthy College Permanent Experimental Field; Stage to Cut Wheaten Hay; Trial of Stone-Gathering Machines; Salvation Jane or Paterson's Curse.

Horticulture: Apple Mussel Scale; Bordeaux Mixture; Cidermaking; Curculio Beetle; Codlin Moth; Currant Industry; Fertilisation of Orchard Lands; Fruit Drying; Fruit Flies; Fruit Preserving; Grape Vine Mildews; Gumming Disease of Peach and Almond Trees; Selection and Planting of Fruit Trees; Irish Potato Blight; Peach Leaf Curl Fungus; Plums and Prunes; Preserving, Canning, and Drying Fruits; Production of Early Tomatoes; Remedies for Diseases of Fruit Trees and Vines; Some Notes on Almonds.

Dairy: Milking of Cows; Spaying of Cows; Taints and Flavors of Dairy Produce; Taints in Milk and its Product.

Stock: Branding of Stock; Stomach and Bowel Diseases of the Horse; Bot Flies and Bots.

Beekeeping Notes.

[Every farmer and fruitgrower should join the Agricultural Bureau. Write to Department of Agriculture for particulars.]

POINTS FOR PRODUCERS.

Use of Artificial Manures.

The Government Statist (Mr. L. H. Sholl, C.M.G.) has issued interesting and instructive tables showing the percentage of the land under crop in South Australia in the seasons 1911-12 and 1912-13 which was manured, and the quantities of manure per acre actually used on the average by the farmers in each division of the State. The tables, which were compiled from returns supplied by farmers and are sufficiently explanatory, are printed below :—

AREA.

Division.	Total Area Under Crops of All Kinds.		Area of Cropped Land Manured.	
	1911-12.	1912-13.	1911-12.	1912-13.
	Acres.	Acres.	Acres.	Acres.
Central	1,004,631	1,027,553	846,673	866,017
Lower North	741,668	781,467	670,525	701,815
Upper North	324,113	295,305	184,018	175,839
South-Eastern	385,594	419,420	330,804	358,761
Western	508,077	538,080	462,753	485,601
Outside counties	1,255	1,173	—	100
Total	2,965,338	3,062,998	2,494,773	2,588,138

QUANTITY.

Division.	Quantity Manure Used.		Average Quantity Used Per Acre.	
	1911-12.	1912-13.	1911-12.	1912-13.
	Tons.	Tons.	lbs.	lbs.
Central	34,398	36,900	91·0	95·4
Lower North	24,891	25,670	83·2	81·9
Upper North	5,222	5,147	63·6	65·6
South-Eastern	10,308	10,883	69·8	68·0
Western	12,656	13.005	61·3	60·0
Outside counties	—	2	—	44·8
Total	87,475	91,607	78·6	79·3

In addition, 16,357 acres were manured with 134,503 loads of stable manure in 1911-12, and 15,003 acres with 111,434 loads in 1912-13.

Conference of Hills Branches.

The annual conference of the Hills Branches of the Agricultural Bureau will be held at Mount Barker on Monday, October 13th. The Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.) has been asked to address the gathering, and among the other officers of the Department who will be present are the Horticultural Instructor (Mr. Geo. Quinn), who will speak on "Some Points in the Care of the Orchard," and the Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), who will invite the attention of Conference to a subject relating to diseases of stock. The activity of the Mount Barker Branch is a guarantee that the arrangements will be well thought out, and that the proceedings generally will be both interesting and instructive.

Poultry-Keeping in Ireland.

Poultry-keeping in Ireland is primarily a woman's industry, says the *Journal of the Board of Agriculture.* Its regeneration has been effected in no small degree through the agency of women. During the past 12 years the educational work has been carried out almost exclusively by women teachers. The success of this systematic attempt to improve the conditions of poultry-keeping in Ireland may be gauged to some extent by a consideration of the increase in exports. During the period from 1904 to 1910 the *average yearly increase* in the value of eggs, poultry, and feathers exported from Ireland amounted to £720,000.

Opossum-Farming.

The newest West Australian industry, so far as the land is concerned, says *The Geralton Express*, is that about to be started by Mr. Lance Le Souef, younger brother of the Director of the Perth Zoological Gardens. Mr. Le Souef is about to start an opossum farm somewhere down in the South-West timber country, and it is reported that he intends to begin operations by importing about 1,000 or 1,500 black opossums from Tasmania. Mr. Mitchell (ex-Minister for Agriculture) once said that he could tell the wheat-growing capacity of the soil by looking at the tops of the trees. If Mr. Le Souef's scheme works well the only possible way to tell the stock-carrying capacity of land will be by looking at the tops of the trees. The Sydney Le Souef is the originator and advocate of the 'possum-farming idea. According to him, 'possums will beat any other kind of stock out of sight as profit producers. At present, however, no one knows how many 'possums to the acre our land will carry.

Largest Walnut Tree.

Yula City, says the *Pacific Rural Press*, has the distinction of having within its limits the largest walnut tree in California, and in all probability in the world. It is known as a Paradox walnut, a cross between the Northern California black walnut and the English walnut. The circumference of the trunk 4ft. from the ground is 15ft. 4in., while the greatest spread of branches is 108ft. The height to the square of the top is 99½ft., and the extreme height to the top of the topmost limb is 103ft. The tree was planted at least 40 years ago, but though it bears a considerable crop of nuts each year, the quantity is insignificant when compared with its size.

Price of Wheat in the United Kingdom.

Statistics issued by the Board of Agriculture and Fisheries show that the average price of wheat in the United Kingdom in 1912 was 34s. 9d. per Imperial quarter, being 3s. 1d. higher than in 1911 and 1910. If the average price (36s. 1d.) reached in 1909 be excepted, the price in 1912 was the highest since 1891, when 37s. was recorded, while all the annual averages from 1885 to 1890 were also lower than in 1912.

Prices of Barley and Oats.

The average price of barley in 1912 was 30s. 8d. per quarter, 3s. 5d. higher than in 1911, and 7s. 7d. higher than in 1910. The 1912 average was the highest recorded since 1884, when the price was the same. The average price of oats in 1912 was 21s. 6d. per quarter, being the highest since 1882.

Co-Operative Dairies.

One of the happiest consequences of the foundation of co-operative dairies in France, says a bulletin of the International Institute of Agriculture, has been the profitable utilisation of the subproducts of milk, which previously brought in nothing or practically nothing to the farmers, in spite of scientific treatment. The dairies have, for example, established pigsties and have given themselves largely to the improvement of pigs, and thus find a profitable use for their whey. Some of the societies have been formed solely for the utilisation of the subproducts of milk.

Potato-Spraying.

Attention to the results of spraying potatoes for several years at the stations of the Irish Department of Agriculture is called in a leaflet. This shows that in each of five years washing soda with sulphate of copper increased the yield of crops to a greater extent than where lime was used. The average increase was 2½ tons where the soda was used, against 1 tons 14cwts. where lime was in the mixture. The contention is that the soda mixture sticks on the leaves better than the other. The directions for preparing the former are to put 35galls. of clear water into a paraffin barrel, which holds 40galls., and to suspend in a piece of coarse canvas 8lbs. of sulphate of copper just below the surface of the water, which is the best way to dissolve it when boiling water is not used. Then 10lbs. of washing soda should be dissolved in another vessel in boiling water and made up to 5galls., to be added to the other solution immediately before being used. The two solutions can be kept for days separately, but would deteriorate if mixed many hours before being used. When mixed, the stuff should be tested with a piece of litmus paper. If the paper turns red, more soda should be added until the paper when dipped in the mixture remains blue.

Co-operation—A Lesson from California.

The orange and lemon crop in California is about 50,000 carloads annually or 20,000,000 boxes, produced by over 10,000 growers. Four-fifths of the growers are organised into co-operative associations, more than 60 per cent. of which are federated into the Californian Fruitgrowers' Exchange. This is a non-profit corporation. It is managed by a board of 17 directors, one from each district of the exchange, who employ one general manager.

Agricultural Education.

The experiment stations in the United States in 1897 employed 628 persons and had a total income of £235,000, while in 1911 they employed 1,567 persons, and their income was £763,000. The number of colleges giving instruction in agriculture in 1897 was 61, the students totalling 4,000; in 1911 the 67 State agricultural colleges enrolled nearly 18,000 students, and there were also 42 privately endowed colleges giving courses in agriculture. There were only nine agricultural high schools in 1897, as against 78 in 1912. Nearly 290 public high schools receive State aid for courses in agriculture, domestic economy, and farm mechanics, and over 1,600 other high schools give instruction in these or kindred subjects without State aid. Agriculture in the elementary schools had hardly been thought of in 1897, whereas now nearly every State in the Union gives some encouragement to such teaching, and 19 require it by law.

Australian Sheep in South Africa.

At the first Annual Conference of the newly-constituted Cape Agricultural Association, which was held at Port Elizabeth on June 4th, 5th, and 6th, the following resolution was carried :—" That owing to the number of inferior sheep imported into this union from Australia, the Government should allow their experts to inspect any imported stock offered for sale at the request of farmers." Referring to the same subject, the Commercial Agent for the Commonwealth, in a report to the Department of External Affairs, states—At its last meeting the Cape Stud Book Society decided to urge the Government of the Union to insist upon inspection at the ports of all imported sheep and their grading into first, second, and third studs, and first, second, and third flocks. The idea was that they should be numbered by a brand " with a view to preventing inexperienced buyers from paying a high price for sheep not worth the money." The society also decided to urge that a South African stud-breeder should be appointed as inspector.

Victorian Fruit Yield.

A return issued by the Victorian Government Statist (Mr. A. M. Laughton) shows that the yield of apples in Victoria for the season 1912-13 was 2,036,756bush. Pears gathered represented 669,898bush., plums 260,830bush. peaches 289,731bush., and apricots 138,881bush. ; other descriptions raising the total to 3,775,400bush. On the area growing fruit for sale 6,285 growers dealt with 59,119 acres

United States Department of Agriculture.

The development of the Department of Agriculture in the United States during the last 16 years and the manifold nature of its operations are shown in the report of the Secretary of Agriculture for 1912, contained in the Department's Year Book. The following will illustrate the growth of the Department in certain directions :—The expenditure in 1897-8 was £682,000, it increased to £1,481,000 in 1905, by 1912 had risen to £4,352,000, and for 1913 is set down at £5,155,000. The staff of the Department has grown from 2,444 persons in 1897 to 13,858 in 1912, and while in 1897 the different publications printed were 424, of which 6,541,210 copies were issued, in 1912 the publications numbered 2,110 and the copies issued 34,678,557.

The Blow-Fly Pest.

A writer in the *Queensland Agricultural Journal* recommends arsenic water of the strength of 1lb. arsenic to 30galls. of water for the purpose of poisoning offal, dung, &c., upon which the flies blow. Thousands of flies are said to be destroyed in this way.

The Importance of Tillage.

Behind every big crop you will find the stuff that made it grow. It may not be all in the form of a fertiliser, but wherever there is a big crop there must be the abundance of available elements to produce it. There are other things than fertilisers that make crops grow. If you are in the field when the crop that makes the remarkable yield is planted you will usually find it is deep and careful ploughing, and repeated harrowing, rolling, and dragging that produce a perfect seed bed—firm below, free from clods, fine on the surface to hold moisture during drought. Continue to watch this crop, and you will find that the tillage is frequent and careful, that there is an extra dose of fertiliser added just before fruiting time. The invariable tendency is to hasten seeding by neglecting tillage, and quite as invariably it is a msitake. A few days in planting have little to do with the yield of crops, but an extra harrowing of the seed bed may mean a great deal. If you must skimp on tillage, do it after the crop is planted, but have conditions right at the start.—*Country Gentleman.*

Soy Beans.

The soy bean is a large bushy plant 3ft. to 6ft. high, maturing in 90 to 135 days. Meal from these beans analyses at least 35 per cent. proteins, 18 per cent. fat, with little indigestible matter. Culture is simple, 1½bush. broadcast or for seed at 4in. intervals in 2ft. rows. Yield, 25bush. to 35bush. per acre ; 1bush. equal in feeding value 2bush. maize. It may follow wheat, but is better after a nitrogenous crop, *e.g.*, lucerne.—*American Agriculturalist.*

Shipping Wheat, Wallaroo.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquirers received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"T. H. S.," Peake, has a five-year-old mare with swelling on side of nostril, which discharges stinking matter, at times shrinks, swells again, bursts, and so on. There is history of a kick. He asks for advice.

Reply—The kick injured a bone, the splinters of which cause the trouble; the wound must be opened and the cause removed, it will then probably heal quickly under ordinary wound treatment.

"J. J.," Forster, asks how to treat a young horse very lame in off side hock, resulting from a sudden jerk at a fence.

Reply—Apparently there is a severe strain of the ligaments and tendons on the inside of the hock. Treatment—Hand rub as often as possible, foment with hot water frequently, apply a lotion made of tincture arnica, 1oz., methylated spirit, 1 pint.

Goode Branch fears that if strychnine is used for rabbits it gets into the bones, and is dangerous to cattle.

Reply—There is some little risk of cattle eating rabbits containing enough poison to be dangerous, but from a practical standpoint, if the cattle get enough natural food to eat the risk may be ignored.

Spalding Branch asks if the red worm found in water troughs is the same as blood worms in horses.

Reply—No; these red worms are harmless, and are digested by the horse; blood worms hatch out in the mud of dams and creeks and are very tiny, white, hair-like worms in their early stage.

The same Branch asks if the action of sulphate of iron, when dissolved in an ordinary or galvanized trough, creates a poison through contact with the iron or galvanized part.

Reply—No ; at any rate, not in the quantity likely to be used.

" Higgerhunt " wants treatment for a four-year-old draught colt passing threadworms.

Reply—Give an enema of a quart of warm milk, two tablespoonfuls of ordinary turpentine, and four tablespoonfuls of glycerine, this will shift the worms that live in the hind gut Probably a drench of a pint of raw linseed oil and two tablespoonfuls of turpentine would shift other worms as well. Give an ounce of salt a day in the feed, and half an ounce of flowers of sulphur once daily for a fortnight.

" S. B.," Warcowie Branch, asks how to treat a two-year-old colt which seems in good health, but has lumps all over it, which vary from time to time, but do not seem to cause it any trouble.

Reply—The animal's blood is out of order ; ¼oz. flowers of sulphur and ¼oz. cream of tartar given once a day in a little food for a fortnight should bring about an improvement.

" J. W.," Wanbi, has a 10-year-old gelding that paws in his stall at times and when loose or in harness, and wants to lie down as if in pain.

Reply—The horse is probably suffering from sand or other intestinal irritant. It would be well to try for sand by giving a quart of new milk or strong coffee.

Green Patch Branch wants treatment for horses having gravel—not sand, but ironstone quartzy gravel up to ½in. diameter—in their bowels.

Reply—Half a pint of castor oil with a similar amount of raw linseed oil may be given as a purge, but the condition is a most serious one, and chlorodyne or laudanum may be required with the oil. Gravel of this sort is not eaten, but swallowed with the drinking water, so that the supply should be protected by fine wire netting or other strainer.

" P.," Clanfield, has an unbroken mare which sustained a severe barbed wire cut on the leg. The wound has been treated, but not very satisfactorily, the leg being swollen.

Reply—Probably a daily dressing of a solution made by dissolving as much pure iodine as will lie on a shilling in a pint of methylated spirit will help to reduce the swelling, which is the result of growth of scar tissue.

" S. H.," Lameroo, has a light horse which struck the leg while jumping leaving a fluctuating swelling above the knee.

Reply—The swelling is an injury to the oil sheath through which the muscle runs. Treatment—As much hot water and hand-rubbing as can be put in every day, followed by a little oleate of mercury, 10 per cent., well rubbed in every evening.

" D. H. C.," Balaklava, has a six-year-old mare suffering from intermittent colicky pains, which continue in spite of treatment.

Reply—Probably a preparation of three days on bran mashes only, followed by a six-dram aloes ball, would be a means of relieving her of what appears to be an accumulation in the large bowel. No work for three days after.

" A. F.," Willowie, has a mare with a rough, fleshy growth on the eyelid.

Reply—This is somewhat similar to a cancer, and originates from the irritation of flies and dust. Treatment is removal by a knife, no other is of any use. If no veterinary surgeon is available, the mare may be thrown, a little 5 per cent. solution of cocaine poured into the eye, and the whole mass with the part of the eyelid it is on cut away, afterwards the eye should be kept clean and a little boracic acid blown on to it every day till well.

Booleroo Centre Branch asks—Is bluestone pickled wheat injurious to horses or poultry ?

Reply—In feeds of 3lbs. or 4lbs. it is often used with good effect as a worm remedy for horses, but if constantly fed would prove harmful after a time. With regard to poultry, it depends entirely on the amount eaten whether it would do harm or not.

" H. H. W.," Pinnaroo, asks for prescriptions for—(1) A general application for cuts caused by barb wire, or for similar injuries ; (2) sand ; (3) colic.

Reply.—(1) A drachm of pure iodine, practically as much as will lie on a shilling, dissolved in a pint of methylated spirit, will be found a very useful follow by 10-drop doses of veterinary tincture of nux vomica twice a day for a fortnight. As a preventive plenty of water and soft food, either green or application. (2) Drench the horse with a quart of new milk or of strong coffee made with milk, grounds and all ; repeat in a few days if necessary ; mashes. (3) Half a pint of gin with a wineglassful of peppermint and half a pint of warm water ; or a pint of raw linseed oil and two tablespoons of turpentine ; or a teaspoonful of household ammonia in half a pint of cold water ; or an ounce of baking soda in a pint of strong coffee. Any of these will be found useful.

The Whyte-Yarcowie Branch reports that a mare in foal died after a short illness, and on a *post mortem* being made it was found that the hinder gut had become tied in a complete knot similar to that tied by a binder. A portion beyond the constriction was much inflamed.

Reply.—Gut tie is usually the result of excessive muscular action of the coats of the bowels, which are generally working slowly with a worm-like movement. This occurs after irritation, which in an in-foal mare may very likely have been caused by the movements of the foal.

" W.," Whyte-Yarcowie, states that he crutched some of his ewes to prevent fly blow, using Cooper's dip ; then, suspecting lice among the sheep, he was surprised to find them only on those not dressed. He asks if the dressing would free the others from lice.

Reply.—Probably, yes, to a certain extent ; complete dipping certainly would, or spraying. The firm in question distribute through their agents literature on both fly blow and lice. A recent pamphlet affirms the marked success of their dips as a preventive of fly blow.

Coomandook Branch inquires cause of illness of calf nine months old, which moped, went blind, and ran at nose with a slimy discharge.

Reply.—The symptoms seem to point to poverty of blood, anæmia, most probably due to parasites. Should other cases occur, 20grs. of sulphate of quinine twice a day in a pint of milk would probably help towards recovery.

" W. R. C.," Wirrabara, has a horse that was kicked just above the knee. This left a swelling, and he asks for advice.

Reply.—Probably a little oleate of mercury, 10 per cent., rubbed in daily for 12 or 14 days, will reduce the swelling.

The Morphett Vale Branch asks for a remedy for a horse troubled with thick urine. A member stated that a dessert spoonful of saltpetre dissolved in water and mixed with the chaff once a week was an effective remedy. The same Branch inquires the cause of a horse rubbing the hair off his tail.

Reply. The remedy suggested (a dessert spoonful of saltpetre in the chaff once a week) for thick urine is good ; or 10 to 15 drops of tincture on a little sugar put into the mouth once a week may be administered. The cause of a horse rubbing hair off tail is generally a kind of mange parasite. Give ½oz. of flowers of sulphur once daily in the food for a fortnight ; wash the places rubbed well with soft soap in the warm sunshine, and then daily apply with a stiff brush (an old dandy) olive oil four parts, petrol one part.

HORTICULTURE.

(Replies by Mr. G. Quinn, Horticultural Expert.)

" B. A. A.," Berri, forwarded orange leaves affected with a scale disease, in regard to which he seeks information.

Reply—The twig and leaves are affected by a species of lecanium, probably *L. Lesperidium.* It favors young, densely-foliaged orange trees and gives rise to much honey dew, upon which in turn the mould fungi thrive. Remedies—Thin out dense spots of foliage and spray with several applications of kerosine emulsion, made by emulsifying in the proportions of 1lb. soap, 1gall. boiling water, and 2galls. kerosine, and diluting one part of the mixture in 10 to 12 parts of water for spraying.

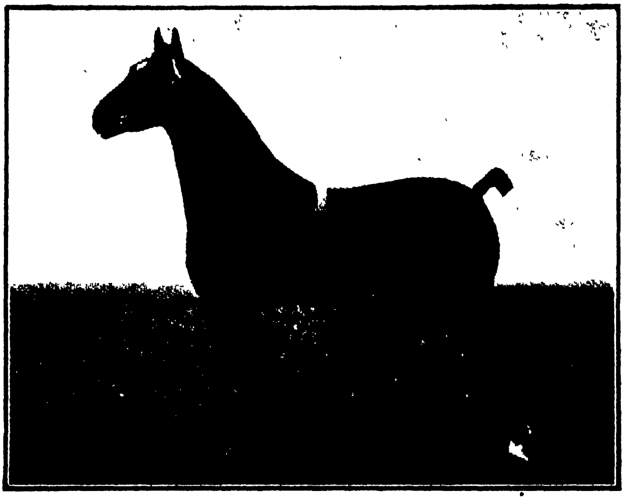
" G. H. M.," Mannum, forwards specimens of a caterpillar found in ripe oranges and lemons.

Reply—The caterpillar forwarded belongs to the Tortrix family of moths, and is probably the larva of *Cacœcia responsana*, a native leaf roller. Although some seasons it may prove troublesome amongst fruit trees and grape vines, it does not usually prove seriously destructive. Its favorite haunts are amongst clusters of newly-formed grape berries, where nectarines or plums bunch together, or when apples are touching. It frequently draws a leaf over the fruit and eats the surfaces of both leaf and fruit, rarely penetrating deeply into the pulp of the latter.

THE PONY ON THE FARM.

By F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.

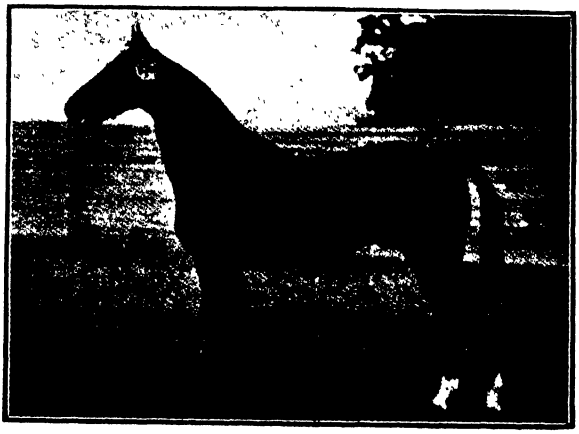
A pony, or a pair of them, is never out of place on a farm ; but sometimes one sees a lanky monstrosity of diminutive horse-flesh, with a head big enough for a draught stallion, and hoofs flat enough for meat dishes, that is too small for the team and too bulky for the sulky shafts, and lost in those of the spring dray ; and one is told that the thing is a pony. If so, the fewer the better, for such ill-judged crosses are no more ponies than they are thoroughbreds ; and should anyone be fatuous enough to possess one his return to reason would be marked when he put a bullet in its brains, or auctioned it with a glowing description and no warranty.



Three Year Old Pony Stallion.
First, Royal Show of England, 1911.

The pony is an example of the survival of the fittest under the most adverse conditions, and could a better character be wished for with any farm servant ?

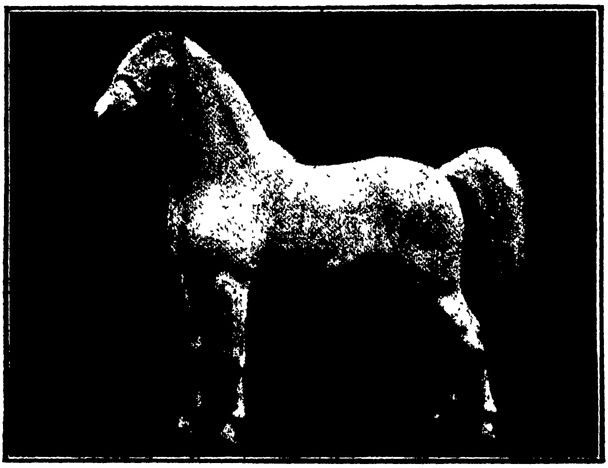
Long before the Phœnician traders tried to over-reach Cousin Jack, and failed, Britons were good horse masters and shrewd breeders. This is evidenced to-day by the old Devonshire pack horse and the Cleveland bay, many examples of which are as like as two pins, and which are described by Roman and Saxon chroniclers as the British horse, which was forced to the hills and moors with his master before the invaders' arms, and there lived the simple life of hard work and short rations. These developed the intellect if they stunted the growth, with the result that a pony is as cunning as a monkey, as docile as a child, as tough as a veteran, and staunch as a horse; he wants little to eat and never tires. He is up to any weight, despite his size, as anyone can see afield with the Devon and Somerset Staghounds on the wilds of Exmoor, where not infrequently the pony is over the bank first, ready to give his 16-stone rider a hand with his tail for a haul up the slope, when the upstanding hunter and his pink-coated mount are "pounded" in the field; while at Brampton fair one may often buy for a few shillings a Dartmoor colt that can be carried home in the railway carriage, and that in a few years will run down his 50 miles before dinner and be ready for the return ere the moon rises.



Polo Pony Stallion, "Othrae."
Champion, Royal Show, 1911.

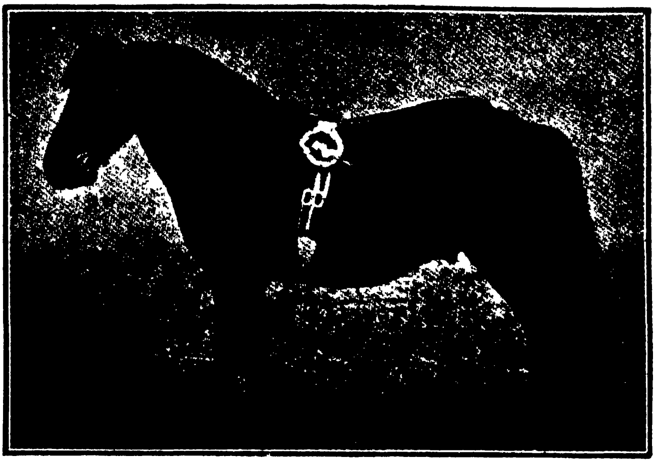
One is told in South Australia that ponies are not strong enough or fast enough for the long distance runs required of them, and yet the writer has often noticed that when the successful man of a district is proudly piloting him over his paddocks the buggy is drawn by a pair of ponies, and rattling good ones, too, as a rule. If one watches the arrivals at Onkaparinga, or any other favorite meeting, the pony teams are always there on time, and their owners do not get out of bed any earlier to do it; the little steel-wire legs have not the stride of the horse, but the pace is the same up hill and down, with always a bit in reserve if a train has to be caught.

If the children are too small to ride, it is a lot easier for mother to take them out in a pony cart than to push a pram, while the pannier will help if the country is rough. As soon as the boys and girls can straddle a saddle, off they can go to school on the pony, which comes up to call and never plays a worse trick than baulking at a mud heap for the pleasure of seeing a cocksure rider take a header into it; while if a message has to be sent a mile or two, the answer will come back much faster if it is taken on the pony, to say nothing of the pride of ownership and the increased interest it creates when "my pony" has been used for some important occasion—to fetch the doctor perhaps, or bring back the result of a successful deal. Then, as boys come back from college and the girls put up their hair, something smarter is looked for and found in the judicious breeding that has evolved a stylish pair for the buggy, or a couple of lithe active youngsters on which the boys can play a fast chukka at polo, and sell at a good profit to the sporting city man. And as the back stiffens and the hairs go grey, it is not so troublesome to throw the leg over the pony, and one is near the ground to see the weeds



Welsh Mountain Pony Stallion, "Greylight."
Champion Royal Show, 1911.

or look over the tilth without the weariness of walking. All these are the ordinary legitimate uses of the pony on the farm, but the stout little beast can do more than these. In a light dray or express the seed wheat can be delivered where it is wanted, and the hundred and one things that always seem to be at the store or station brought home without delay ; while a small-sized horse gear can be cheaply fitted to the separator or the churn, to say nothing of the washing machine or the centrifugal pump, all of which will be worn out long before the pony that supplies the motive power, while a gentleman like " Greylight " in the home paddock is always a sight for sore eyes.



Shetland Pony Stallion, "Silverton of Transy."
Many times Champion at the Royal Show.

The points of a pony are those of the horse refined, his faults are those of the horse minimised, his price is half, and his value double.

* * *

SOME ECTO-PARASITES AFFECTING POULTRY.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

(*Continued from page* 18.)

Dermanyssus, Dugès. (Order Acarina—Family Gamasidæ.)

GENERAL DESCRIPTION.

Neumann says of this family, " The integument is coriaceous, partially or wholly, and has two chitinous plastrons ; a superior dorsal, and an inferior ventral which give attachment to the legs. The rostrum is arranged for pricking or sucking, the chelicerae are generally disposed as didactylous pincers, and are usually dissimilar in the two sexes ; the maxillæ are fused

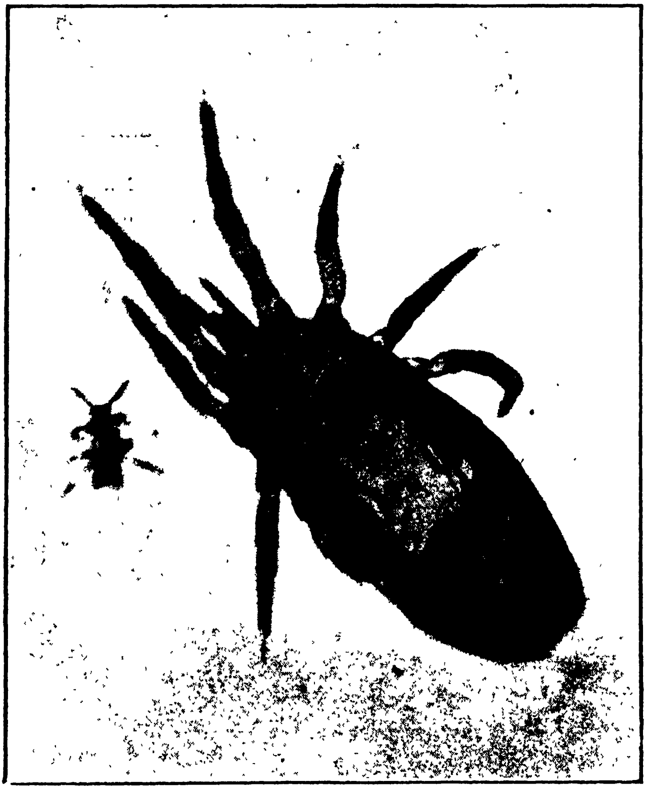


PLATE I.

into a perfect tube on the upper surface by the labrum, which is festooned; the maxillary palps are simple, free, antennæ-like, composed of five articles, and provided inwardly with galeæ or secondary palps. The legs have six

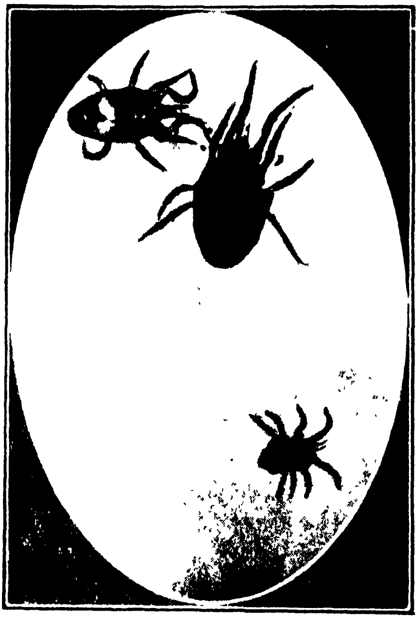

Plate II.

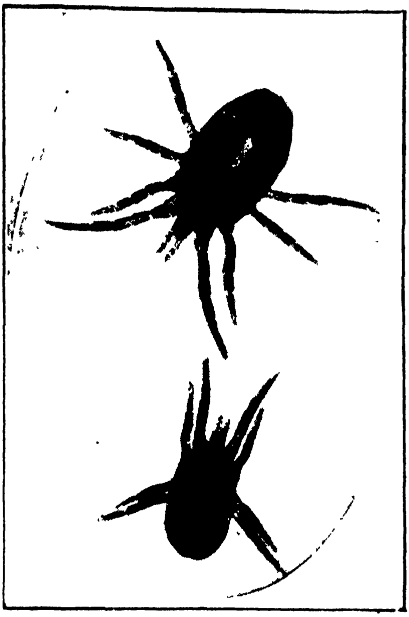

Plate III.

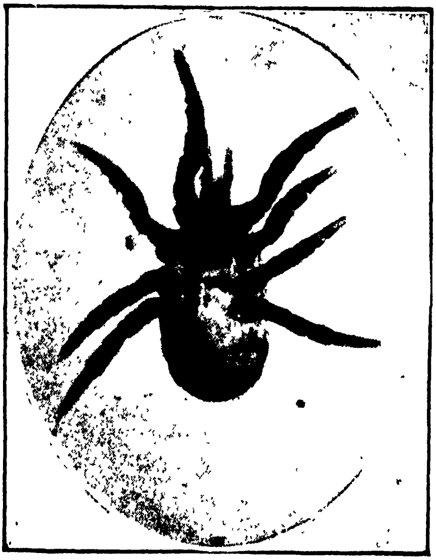

Plate IV.

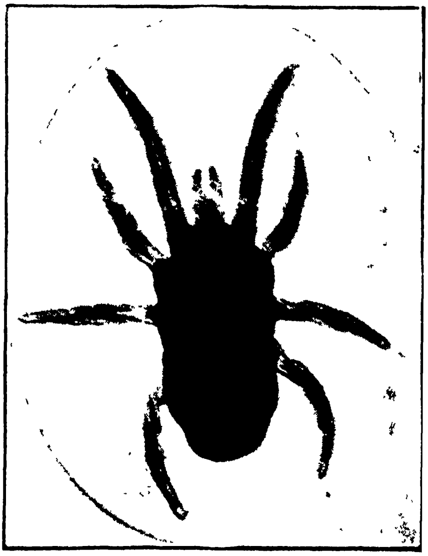

Plate V.

articles, terminating by two hooklets and a trilobate membraneous caruncle. There are two stigmata, situated near the posterior legs and protected by a very long tubular peritreme, lying along and above the haunches and opening in front. There are no eyes. They are oviparous."

This species is a partial parasite of poultry, and also extends to man and domestic animals.

Demanyssus Gallinæ, Redi.

Body ovopyriform, posterior end largest, slightly flattened from above to below; abdomen margined by short, well-separated bristles; color varying from yellowish-white or grey to blood red, according as this parasite is fasting or more or less full; the intestinal tube gorged with blood can be seen as a variously shaped figure. The ovigerous female is ·70 mm. long by ·40 mm. broad, the male ·60 mm. long and ·30 mm. broad. Many specimens, however, exceed these dimensions. The chelicerae of the female is in form of a long thin stylet, that of the male subdidactylous. The *Dermanyssus*, commonly known as the red poultry mite, is essentially noctambulatory, and in the daytime lives in cracks, under the perches, in rough walls, straw, bags, or wherever it can effect a hiding. There is no doubt that the *Dermanyssus* of birds (particularly canaries), and termed *D. Avium* (De Geer), and of swallows *D. Hirundinis* (De Geer), are identical with *Dermanyssus gallinæ*. I refrain from quoting the many cases recorded of the invasions of man and animals, but it is worthy of mention that horses and cattle may be affected with a

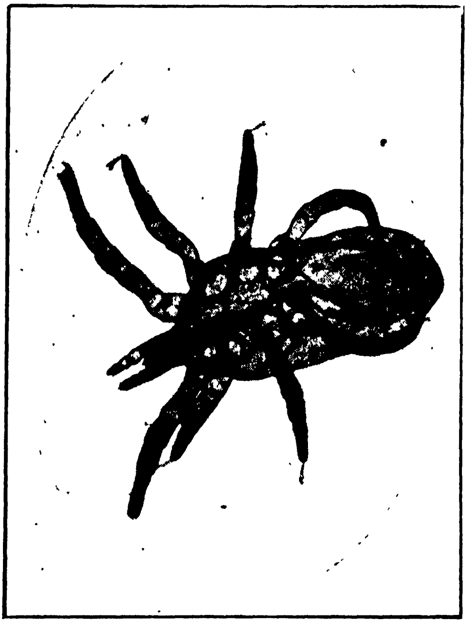

PLATE VI.

peculiar dermatosis which may or may not be serious. This trouble is due to the depredations of this pest, which, if unchecked, soon appears in countless numbers.

AMONG POULTRY.

This parasite seems cosmopolitan, and is troublesome wherever poultry are kept. His great confrere, *Argas persicus*, is found only under certain climatic conditions and surroundings. Like *Argas*, *Dermanyssus* can undergo the most protracted fasts, and is at all times ready for a feast. They breed with extraordinary rapidity, and in a small space there may be congregated thousands in all stages, from minute eggs onwards through the almost transparent larvæ, then the nymphæ, and on to the adults. Surrounding them is a mass of greyish powdery material consisting of general detritus, such as moulted chitin, excreta, and dust. Although not yet proved to be carriers of harmful organisms, such as is the case with the ticks, their general habits should render suspicion justifiable. But there is, of course, the liability to secondary invasions of other ecto parasites, such as microscopic fungi. Poultry pluckers absolutely abhor them, and those who come in contact with them through handling infested poultry at night are to be commiserated The extraordinary numbers in which they congregate and their rapacity as bloodsuckers soon lead to an anæmic condition among infested poultry. It is usual to look upon the effects of these depredations as due to loss of blood.

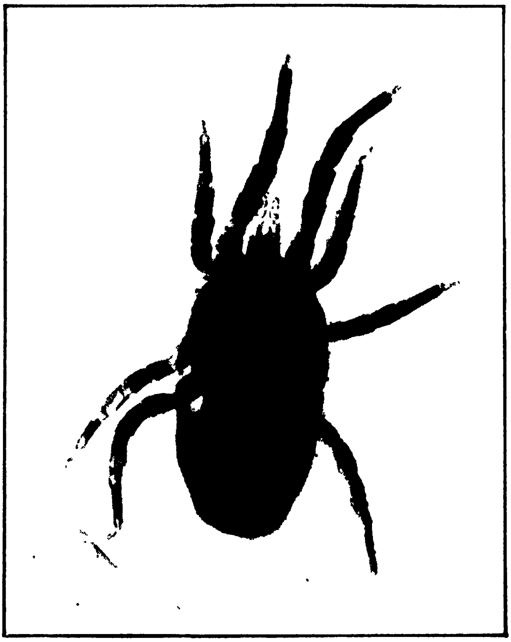

PLATE VII.

Their swarming hordes, however, produce a state of irritation that soon reacts upon the hardiest fowl. Of course, it can be understood that the physical effects of their mere presence on the body of the fowl, added to that of their numerous punctures, will seriously affect metabolism. Further investigations will probably, at the hands of the chemist, show that these disturbances are due to chemical changes and doubtless to specific poisons.

Remedial Agents.

When thorough measures are adopted I have never known any trouble in eradicating red mites from a poultry-house. Numerous insecticides will kill them at once, and like the tick, they succumb to the cheap and odorous kerosene. Sitting hens require periodic examination, for, although these pests are said to be noctambulatory, they will infest a sitting hen in the daytime; and in this respect I have seen gruesome sights of dying, neglected, sitting hens absolutely swarming with thousands of the pest. The use of wooden boxes, such as grocery boxes, &c., as nests is to be deprecated, for, if infested, they will need saturating with kerosene emulsion or some other insecticide. Brooders, and even incubators, have been known to be infested; the first intimation was the sickly appearance of the chickens, some of which were swarming with this rapidly-breeding parasite.

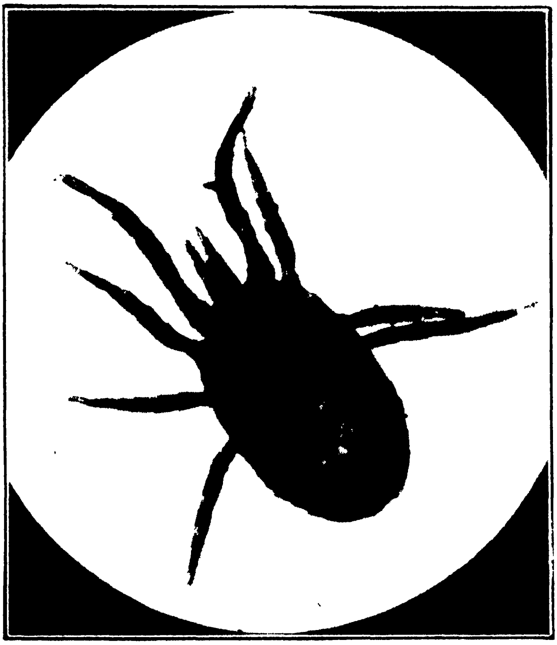

Plate VIII.

Plate IX.

Among poultry breeders many curious theories are current, due, as a rule, to inaccurate observation. The unfed adult *Dermanyssus* is a minute organism. In the early larval and nymphal forms they are invisible, except to persons of very keen eyesight. Eggs transferred from a nest and placed in an incubator would account for the machine becoming infested, as there might be several of the parasites on the eggs and yet escape notice. As with the poultry tick, *Argas persicus*, the adult *Dermanyssus* commonly carries larvæ firmly attached to its body. Frequently, on transferring a live adult to a watch glass of alcohol, it has been found, on examination under a moderately low power, to have one or more larvæ attached. The eggs are very minute, and are ellipse-shaped. The tarsi (end of legs) terminate in a peculiar caruneulation, which is furnished with hooklets, so that the parasite can attach itself to feathers, skin, &c., by the hooks, and adhere to smooth surfaces by aid of the carunculated pads. The stylet, peculiar to the female only, and forming portion of the rostrum (beak, or sucking organ), is a very fine and delicate organ, and practically does not admit of photographic reproduction ; it appears faintly in Plate VI.

PLATE X.

WARNING TO FARMERS.

It is a common practice on farms to allow poultry to roost in sheds where cattle and horses are fed, &c. Neumann quotes many cases of cutaneous affections in cattle and horses, and also a case where the inner ear of a cow was found, on *post-mortem*, to be invaded by *Dermanyssus*, which had tunnelled through, and were the indirect cause of death. Very probably many unaccountable deaths among stock may be due to the same pest. On all farms, as well as in poultry-yards, vigorous measures should periodically be taken to eradicate this and other parasites. For such purpose various sheep dips and disinfecting fluids are of service. Where the sheds are of timber, roofed with straw, the use of kerosene, and even kerosene emulsion, will certainly add to danger from fire. Formalin used as a 10 per cent. solution is very effective, and as it is cheap, can be freely used. Many cases are on record of infested dwelling-houses, &c., in such cases formalin is well suited. Bird cages, nest boxes, &c., should be immersed in a tubful of the mixture and allowed to soak for some hours, so that all cracks may be saturated.

Plate XI.

Unless this be carefully carried out the fluid does not penetrate to the hiding-places of the parasite. Superficial spraying and cursory applications of any germicide are so much energy misapplied, hence the reported difficulty in eradicating. Many people seem content to resort to occasional applications of insect powders, or use patent nest eggs containing carbolised powders, etc. The only rational method is to eradicate all pests, invade their strongholds and resorts, and adopt thorough measures. Remember, these parasites are carried from place to place, either as eggs, larvæ, nymphæ, or adults. The carriers may be poultry and birds, or they may come in crates, coops, bags, &c. There is no such thing as spontaneous generation, as seems a too common belief. It is always a good plan to dip the fowls, choosing a warm day. If then, at the same time, the houses are thoroughly treated, there should be no difficulty in the way of complete eradication.

FORESTRY IN AUSTRALIA.

SOUTH AUSTRALIA.

By H. HUGH CORBIN, B.Sc. (Lond.), B.Sc. (Edin.), Department of Woods and Forests, South Australia.

(Continued from page 40.)

IMPORTATIONS OF TIMBER.

The following indicates the more or less steady increase of imported timbers, and it is obviously coming chiefly from the following countries :— New Zealand, Norway, Sweden, United States. Further, since South Australia is only one of the large number of importing courtries, what must the total exports from these countries individually be ? Probably much more than they can conservatively afford. The total " cut " within each is much greater. Further, the bulk of the imports is coniferous timber, and, as before stated, although South Australia cannot grow these identical timbers it can develop timbers which will satisfactorily take the place of a great deal of the importations. This will not, of course, strike the timber merchant very favorably. He may never have had much to do with timber outside buying and selling and converting it.

Speaking quite generally, timber buyers will only view with favor large quantities of clean, well-grown timber and of a kind that is already known to the trade ; hence it is not surprising that the small quantity of South Australian timber, which has become unsound through neglect, is not appreciated. There is, however, not the least doubt that South Australia is capable, from the point of view of soil and climate, of producing adequate quantities and suitable varieties of timber for most purposes. The great trouble, however, is that before commercial quantities of good timber can be obtained from plantations at least 20 years must elapse : more extensive plantation and natural regeneration areas will be necessary to cope with the demand even if it has not increased by then.

VALUE OF TIMBER IMPORTED INTO SOUTH AUSTRALIA, AS DECLARED AT H.M. CUSTOMS, PORT ADELAIDE.

1905, £194,546; 1906, £240,637; 1907, £323,263; 1908, £543,784; 1909, £395,315; 1910,*£301,971; 1911, *£386,707—total, £2,386,224.

FACTORIES WORKING IN WOOD IN SOUTH AUSTRALIA IN 1910.

In 1910 there were 98 establishments working in wood and 1,716 hands employed. There were four basket and wicker work factories working and 62 hands. There were four brush factories working and 63 hands.

Timber sawn in South Australia in 1910:—Sawmills (town), 43,960,000 super. ft. valued at £510,663; sawmills (forest), 1,338,212 super ft. valued at £9,652.

FIREWOOD.

It is impossible to ascertain the quantity of firewood used in the State yearly. Probably a small fraction only of the total consumed is conveyed over the railways. The quantity of firewood conveyed over the South Australian railways for the 12 months ending June 31st was—1910, 171,467 tons; 1911, 116,709 tons; 1912, 125,684 tons. Could not landholders in certain localities profitably combine the production of firewood and fence posts on some of their holdings?

TIMBER USED IN MINING IN SOUTH AUSTRALIA.

In South Australia alone there are at least 15 mines utilising large quantities of timber as pit props, &c. The following indicates in money value the quantity:—The Broken Hill Proprietary Company, Limited, has expended during the last 10 years £211,000 on timber, which averages about £21,000 per annum. These figures appear in the reports and statement of accounts of the mine issued half-yearly. Most of this timber is imported Oregon, and is not Australian bush timber. It seems that sufficient bush timber cannot be conveniently obtained.

The quantity of South Australian bush timber used in the Wallaroo and Moonta Mines and Smelting Works during the last 10 years was—1903, £6,249; 1904, £7,016; 1905, £6,553; 1906, £8,989; 1907, £10,810; 1908, £8,220; 1909, £8,077; 1910, £8,160; 1911, £11,362; 1912, £12,356—total, £87,792. This statement was kindly furnished by Mr. F. C. Ward, Department of Mines. Mr. Ward estimates that probably £20,000 has been spent yearly on the same class of timber in other mines in South Australia.

---

*Oversea imports only, inter-State trade not included.

SLEEPERS.

Sleeper timber in this State is rapidly decreasing. Among railway engineers in all parts of the world the concensus of opinion seems to be in favor of the use of wooden sleepers for railways, except in a few specially bad localities, where there is some specially active wood-destroying agent, *e.g.*, white ants, and even in these places much may be done by treating the sleepers before putting them down. There is no doubt that in ordinary localities, especially where wood is available, wooden sleepers are cheapest and most satisfactory if the more durable species or those which have been treated are selected carefully. The average price for red gum (*E. rostrata*) sleeper is, broad gauge, 4s. 11d.; narrow gauge, 2s. 8½d.

Number of sleepers used in South Australian railways, 1904-1912—Wooden, 2,298,294, costing £436,563 4s. 7d.; annual average 255,366 = £48,507 0s. 6d. In addition, number of metal sleepers used 1910-11—335,861, costing £111,556.

Until 1908-9 red gum sleepers were used, and after that time both jarrah and red gum sleepers were used. In other words, jarrah sleepers had to be imported, as it was no longer possible to find enough locally sawn red gum sleepers.

WOOD-PAVING IN ADELAIDE.

The number of jarrah blocks used in Adelaide up to December, 1912, is 1,595,800, at a cost of 10 guineas a thousand—£16,755. The proposed paving of North Terrace from King William Street to Blyth Street will take 285,000 wood blocks, and these will cost £2,992 approximately.

WATTLE-BARK.

It is also seen that Australia does not produce bark in sufficient quantities for exportation and its own consumption in certain years. Further, Natal and the other South African States are growing the Australian wattle, with black labor, on open veldt, which does not need any clearing. Annually increasing quantities of wattle-bark are put on the market at cheaper rates than Australia is apparently able to do. This trade is slipping out of Australia's grasp.

Further, Australia imports leather in many shapes and forms, while it certainly has the means to supply its own demand, and also to export bark and hides.

Of course, scarcity of labor and the high cost of labor is undoubtedly the reason why these industries cannot compete with similar ones of other nations. **It is, however, interesting and instructive to note that in 1908 1,935 tons and in 1909 1,401 tons of wattle-bark were imported from South Africa into Australia.**

Value of Wattle-Bark Exported Yearly from South Australia.

Year.	Value in £.	Year.	Value in £.	Year.	Value in £·
1840	—	1864	5,900	1888	41,299

1863	5,969	1887	56,987		

*These figures only represent oversea exports, since no inter-State transfer is recorded after 1909.

Buying Price of Wattle-Bark.—1903-4, £6 15s. ; 1910, £6 ; 1911, £6 10s. ; 1912, £7 ; average, £6 11s. per ton approximately.

Value of Wattle-Bark Imported into and Exported from the Commonwealth, 1901-1910.

	1901.	1902.	1903.	1904.	1905.	1906.	1907.	1908.	1909.	1910.
	£	£	£	£	£	£	£	£	£	£
Imports	616	128	186	340	632	58	156	16,289	12,774	5,461
Exports	48,514	54,607	61,013	93,927	189,699	162,453	132,342	102,410	91,945	119,254

Production of Wattle-Bark in South Australia.

Year.	Tons.	Year.	Tons.	Year.	Tons.
1901–2	8,566	1905–6	8,506	1909–10	5,346
1902–3	9,212	1906–7	7,274	1910–11	6,598
1903–4	8,173	1907–8	7,787		
1904–5	7,343	1908–9	6,889	Total	73,694

Average annual production = 7,300 tons. The average price per ton of wattle-bark for the years 1901-10 is £6 11s.; therefore the total value of bark produced for 10 years = £482,674. **Average value of bark produced per annum = £48,267.** This bark is produced haphazard, and therefore the amount varies from year to year. Given suitable labor conditions there seems no reason why much more should not be grown, especially seeing that enormous numbers of raw hides are exported untanned and much land is entirely suitable for the purpose of growing the tanning bark.

1893	22,976 "	9,304	1902.....	15,537 "	74,554
1894	40,485 "	12,569	1903.....	12,135 "	70.581

Some years ago wattle seed was sent from Australia to South Africa, with the result that Natal has been a successful grower and exporter of tanning bark, and the above figures indicate the development of the industry. Of course, the climate is good for wattles and the labor is cheap, being mostly black labor.

Wattle-Bark Exported from British South Africa.

1906.	1907.	1908.	1909.	1910.
Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
34,999,406	54,478,492	55,661,949	80,127,399	92,610,026
£	£	£	£	£
91,856	139,397	134,563	194,699	219,433

This indicates a high rate of increase, which seems practically steady. There is no doubt that South Africa is gaining what the Commonwealth is losing in this industry.

---

* These figures are copied from J. H. Maiden's publication on Wattles.

CO-OPERATIVE PURCHASE OF BULLS.*

A DENMARK DEVELOPMENT.

Associations for the co-operative purchase and use of bulls in Denmark date from 1874, in which year the first cattle-breeders' association was formed in Jutland. A second association was formed in 1881, but the increase in the number was slow until 1887, after which rapid progress took place in all parts of the country. There are now more than 1,300 associations of cattle breeders in Denmark, with over 1,500 really good bulls.

It should be explained at the outset that the work of the associations is not solely for the purpose of obtaining, at a low cost to the members, the use of a good bull, but is also directed to improving the quality of the herds, and as such has been fostered by the Government, many of the schemes of the latter for the improvement of the livestock industry of the country having been built on the work of the associations.

The associations are local, and their membership varies from four to 60, the average being about 24. One or more bulls of recognised breeding may be purchased, the purchase being usually made with borrowed money, which is paid off after a period of four years, this time being the bull's average period of utility. As the members of the association generally own more cows than their bull or bulls can serve, a local judging committee is appointed, which, together with an expert employed by the "joint management" of several associations in common, visits each member and selects a number of cows worthy to be bred to the association bulls, in proportion to the size of his herd and the total number of cows in the association.

The bull is, as a rule, stationed with the member who submits the lowest bid for keeping him, the price varying from about £10 to £19 per annum.

Assuming that the bull costs £56 (an average price), that its serving capacity is four years, that its sale value is £24, that the members of the association own 80 cows with a service fee of 4s. 3d., and that the bull is awarded a prize at each of the yearly shows, a typical balance-sheet of an association would be as follows :—

---

* From a report by His Majesty's Chargé d'Affaires at Copenhagen, and *United States Bureau of Animal Industry*, Bull. 129. Reprinted from *Journal of Board of Agriculture*.

Income.	£	s.	d.
State subsidy	5	10	0
Proportion of sale value	6	0	0
Prize at annual cattle show	3	10	0
Service fees from 80 cows at 4s. 3d.	17	0	0
	£32	0	0

Expenditure.	£	s	d.
Yearly instalment on purchase price	14	0	0
Interest	1	0	0
Fodder and keep (average)	13	5	0
Veterinary surgeon's fee	0	10	0
Insurance	1	5	0
Show expenses	1	5	0
Contribution to the "joint management"	0	15	0
	£32	0	0

The insurance mentioned in this statement is usually made with a special co-operative insurance company, and protects the association from losses which might be incurred by accident, sickness, or death of the bull. As regards the yearly instalment of the purchase price, the individual members are responsible for the payment of this in proportion to the number of cows each has registered in the association. The effect of the association being started with borrowed money is that it is possible for farmers with small means to participate.

The State subsidy (averaged above as £5 10s.) may amount to as much as £8 per annum for each bull. The grant is given on condition that the bull is examined by a veterinary surgeon twice every year ; that the best cows of the members are selected by the committee to be served by the bull ; and that the committee at least once a year inspects all the herd in the association in relation to their health. Further, the bull must have received a premium or " recognition money " at a Government show, or at a breeding association show supported by the Government. It should be explained that a large amount of money is set aside by the Government for premiums at shows. The " recognition money " is money distributed in respect of bulls which do not receive premiums, but which are considered worthy of recognition as good bulls. A bull to be eligible for Government aid must, furthermore, win a premium every year at a breeding association show until such time as his offspring receive premiums, or, after having reached the age of three years, he must at least be found worthy of a premium at a Government show. No aid is granted before the bull reaches the age of 1½ years, and then only as long as he is in possession of his full breeding capacity. In case a bull is sold, the Government aid can be retained if the association, within two months after the sale, buys another bull meeting the above-named requirements. A complete report from the association is required by the Government at the end of each year.

The extent to which this Government aid benefits the associations will be evident from the typical association balance-sheet quoted above. In the absence of the State subsidy and the show premium, the service fee would have to be raised to over 6s. per cow. It must not be thought, however, that all the associations receive Government aid. There were, in 1906, 30 co-operative breeding associations which did not receive Government aid, and were consequently not subjected to Government supervision. Additional aid may be obtained by the association both for special work in developing good families and for keeping records of the yield of milk and butter-fat and the food consumed by individual cows in the herd.

The following extracts from by-laws of cattle-breeders' associations under common management on the Island of Funen may be given as typical of the rules under which these associations work :—

" The aim of the cattle-breeders' association is to produce the sure and rapid development of a sound, well-built, productive Red Danish breed of milch cows. The aim shall be reached principally by the purchase of meritorious herd bulls, by selecting the best dams (the selection being, as much as possible, based on information about yielding capacity and pedigree), by a rational treatment of the offspring, and by the holding of local shows.

" Every cattle breeder within the district is eligible to membership who subscribes to these by-laws and has in his herd at least one cow which is considered by the management of the association to be worthy of joining the ranks of the breeding animals.

" The management of the association shall be vested in a board of directors. . . . The board shall direct, purchase, offer for service, exclude, and sell the herd bulls of the association, select the cows of the members, act as judges at the local shows, and give members advice regarding their book-keeping. . . . The board of directors or a committee of the members shall, once a year, inspect the herds of the members on their farms.

" The herd bull must be sound and well-built, of Red Danish milking breed, and recognised good pedigree. He shall be insured, and twice a year shall be examined by a veterinary surgeon. He should not be utilised for breeding purposes until he reaches the age of 1¾ years. When purchasing bulls, the association should secure guarantee of breeding capacity. The bull shall be exhibited every year until he shall have received premiums on account of his offspring. Until the age of 3 years he shall be exhibited at a breeding association show subsidised by the Government; and after the age of 3 years at the Government show. He shall also be exhibited at the local shows.

" The members are entitled to have their cows served by the association bull, provided that the cows are not subject to abortion, are otherwise healthy, and are approved by the board of directors.

"The fee for service shall be determined every year by the board of directors, and shall be paid by the members in proportion to the number of their eligible cows.

"Every member must keep the records directed by the board of directors, and is bound to exhibit, at the local shows arranged by the board of directors, all selected cows and their offspring by the association bull until the heifer becomes pregnant for the first time and the bulls reach the age of 2 years. Calves less than 3 months old need not be exhibited. Each calf shall be earmarked with the number of its dam, according to a method adopted by the management.

"The members shall be bound, on the demand of the board of directors, to exhibit the offspring of the association bull, if such are in existence, at the annual offspring shows preceding the Government shows.

"The cows shall be selected and a record kept in the selection book. Only healthy animals shall be admitted."

Carting Grapes.

POULTRY NOTES.

By D. F. **Laurie**, Government Poultry Expert and Lecturer.

OPERATIONS FOR SEPTEMBER.

Hatching should be in full swing In the earlier northern districts the end of September or the first week in October is late enough for chickens, except a few required for special purposes. Ducklings may still be hatched, and if well fed will be in time for the Christmas trade. Goose and turkey eggs may also be set. Carefully select the eggs required for hatching. Firstly, do not set any eggs unless you know that they are laid by hens of special merit. Do not use pullets' eggs for hatching—the results will be poor. If you wish to breed layers, obtain eggs laid by hens of tested laying strains. If you are breeding for table you should select eggs from standard specimens of the following breeds:—Orpingtons, Faverolles, Plymouth Rocks, Wyandottes, Langshans, Dorkings. Or the following crosses may be resorted to for the production of good table birds:—Indian or Old English Game cock and hens of Orpington, Rock, Wyandotte, Faverolles, &c. There are other crossbreds, but these include the best and most easily obtained.

Rearing the Young Stock.

Outside brooders with ample range provide the best conditions. At Parafield there is a sample brooder, which is giving excellent results. Forty or 50 chickens are placed in it and confined for a few days. They are then given full liberty and roam all over the place, often straying 150yds. from the brooder, but are always able to find their way back again at night. Where a good run is not available supply plenty of scratching litter for the birds to exercise themselves in. Plenty of green food, both chaffed and long, must be provided, also grit of all sorts, and a good variety of food, including some animal food. Keep the chickens hard at work scratching and feeding, and you will be delighted with their growth. Fork over some ground for the chickens to scratch in—they enjoy the occupation, and find worms, insects, &c.

Vermin.—Keep a sharp look-out for vermin of all kinds, and eradicate them without fail. Chickens reared by hens are generally infested, and if neglected may die. Kerosine, sheep-dips, coal-tar mixtures, &c., are all good for use on the houses, coops, &c. For infested chickens apply a liberal dressing of some good insect powder.

Separate the Sexes.—This should be done early in the case of the light breeds, such as Leghorns. The little cockerels can soon be distinguished, and when six to eight weeks old are far better in a yard by themselves. The pullets thrive better when yarded separately. Leghorn cockerels about 12 to 14 weeks old, and weighing 3lbs. upwards, will sell at fair prices until Christmas. Select those which are to be kept as breeders, and fatten the rest and market them as soon as fit. It does not pay to hold on to any table poultry after they are fit for market.

MARKET EGGS.

Eggs should be collected once daily, although twice is better in hot weather. All eggs for market should be infertile. The infertile egg keeps indefinitely, and is therefore worth more to the trader, although he is slow to recognise the fact. Any dirty-shelled eggs should be washed in clean water and then dried with a clean cloth. Stains may be removed by rubbing with salt. Do not market any very small eggs, or those with rough shells. Take some pride in the quality of your produce.

Patent Egg Crates.—In answer to numerous inquiries and for general information, it may be stated that egg cases, to hold 25doz. eggs, complete with fillers and wood-wool pads can be obtained from the Manager of the Produce Department, Adelaide, price 2s. 6d.

MARKETING BIRDS.

Many of the crates in which poultry are forwarded to market are a disgrace to the consignors. Allow plenty of head room for fowls and ducks. The crates should be at least 18in. high. Provide a good supply of fresh water in suitable vessels. Allow a fair amount of space, but not too much, otherwise the birds get knocked about in transit. Use decent crates, and have them returned. Put your name and address upon the crates, and address them clearly, giving the number of birds you are forwarding. Always send a postcard to the person to whom you are sending the birds, so that he is duly advised when to expect them, and the number also. Grade your birds. Do not mix old and young, fat and skinny together. If you do the price will be based upon the worst specimen. See that your birds are healthy, and free from tick and other vermin. Should diseased or tick-infested birds be discovered in a market they will be seized and destroyed, and the sender is liable to prosecution.

Good Prices are now being obtained in the Adelaide markets for table poultry of good quality. This is always a period of scarcity, and therefore of good prices. Breed in March and April and you will have a big supply ready for such good markets. Eggs have realised good prices all through, and it is to be hoped that the good market will be maintained.

All-Round and Heavy Breeds.

The committee of the recently-formed General Purpose Poultry Society is busy organising a most comprehensive scheme, as outlined by me, and handed to representative breeders to act upon. The main objects of the society are to promote the breeding of the all-round, or general purpose breeds, and to organise a series of tests to show their respective values. When the scheme is matured I will discuss it at length. All breeders should support the movement, as it is in their interests. The secretary is Mr. A. J. Todd, c/o Messrs. J. Hains & Co., Port Adelaide. The breeds concerned include all varieties of Orpingtons, Wyandottes, Plymouth Rocks, Dorkings, Old English and Indian Games, Malays, Langshans, Faverolles, Rhode Island Reds, Sussex, &c. These breeds generally include good laying strains —*i.e.*, the general average production of eggs is sufficiently profitable when the superior value of the breed for table poultry production is taken into account. The objects of the club are, of course, limited to pure breeds. It costs no more to breed pure stock than it does to breed crossbreds, and there is this advantage—there is generally a good demand for pure stock. Therefore the best can be reserved for sale as stud or show stock, and the others can be fattened and sold as prime table birds. It is well known that the above breeds have given excellent results. It is generally the personal factor which makes for success. The club will not encourage those strains which have been bred purely for egg production at the expense of type, flesh, &c. For egg production alone you select another breed, as stated.

To Prospective Breeders.

A number of people who intend embarking in poultry-breeding on a more or less extended scale have recently consulted me on the subject. It is now too late in the year to begin breeding. It is, however, the right time to decide upon an early start next autumn, and the intervening time may be well occupied in deciding upon a suitable locality, and in erecting the necessary plant. Stock birds should be obtained in January or February, and accustomed to new conditions, so that they are laying in March. It takes considerable time to arrange all the details of even a small plant. Larger concerns cost a considerable sum of money in labor and material. Many people leave matters until the last moment, when an attempt to rush matters ends in failure. I hope to issue shortly an illustrated bulletin on poultry-housing and yard-construction. The standards advised by me have proved their excellence, and are becoming universally adopted. The adoption of standards simplifies the work of laying out and construction.

Suitable breeding stock must also be arranged for some time before it can be obtained. It is courting failure to do as some do, viz., buy anything with feathers upon its back. None but carefully-selected stock will prove a profitable foundation for a successful poultry farm.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1913-14.

[Started April 1st, 1913, to terminate March 31st, 1914.]

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

Decreased Number of Competitors.

On the 31st of July the eggs laid by each pen were weighed. It was found that four pens were disqualified and were then returned to their owners. There are now only 151 pens, or 906 pullets, competing. The total number of eggs laid by these four pens until July 31st has been deducted from the grand total number of eggs laid.

Health.

All the birds are in good health and are looking very well. There have been no cases of sickness during the moth. As may be expected when dealing with over 900 birds in full lay a number of deaths occured. During the month 10 birds died. Two were found dead, evidently from apoplexy; four were the victims of cannibalism, which has been a trouble in one or two pens; two died from severe strain in laying; one died of rupture of oviduct and internal hæmorrhage; and one wasted away (tuberculosis).

Broodiness.

In Section 2 there were 17 cases during the month, as follows:—Six Black Orpingtons, three Buff Orpingtons, three Silver Wyandottes, two White Wyandottes, three Langshans. In Section 1 one White Leghorn went broody.

The Weather

During the month was generally fine and dry; mild temperatures were the rule. The rainfall for the month totalled 1·21in.

Visitors.

Thirty breeders and others visited the poultry station.

Egg Production.

During the month the daily totals have shown steady and satisfactory increase, and before long the production will reach its maximum. The average per pen of six pullets shows an increase of 30 eggs, compared with last year's test. This satisfactory return is from 151 pens, as against 134 pens last year. Nineteen pens have laid more eggs than were laid at the same date by the pen which the year before last made the famous record of 1,589 eggs.

THE YARDS

Are now in course of erection, and during September the birds will be gradually accumstomed to outside conditions. Each yard will be enclosed by a windbreak fence. The lower portion is of galvanized corrugated iron sunk a few inches in the ground. To this iron windbreak the wire netting is attached and fastened to the posts. Each yard is 9ft. by 40ft. and will be well sheltered. Oats, barley, and rye have been sown in the yards and will provide a little green picking. Later on the yards will be well supplied with straw scratching litter.

FEEDING.

The usual rations are maintained without alteration. A fair supply of green food is available, sufficient for all requirements. A considerable area of lucerne has been sown for future use; some thousands of kale plants have been set out; rye and barley are making fair growth, and other fodders will soon be sown, so that a constant supply, and in variety, will be available.

D. F. LAURIE, Poultry Expert and Lecturer.

EXTRACT FROM TRADE COMMISSIONER'S REPORT.

ROYAL AGRICULTURAL SOCIETY'S SHOW, BRISTOL.

The Royal Agricultural Society's Annual Show was opened at Bristol on the 2nd July, and remained open until Saturday, the 5th. The weather that obtained was everything that could be desired, and accordingly the attendance was almost a record one, the number registered on the Friday, being 78,000, and the average attendance for the five days about 50,000 per day.

On Friday, the 4th, the show was visited by His Majesty the King, who took a particular interest in the oversea section of the show.

As requested by the Premier (the Hon. A. H. Peake) when he visited Bristol, I endeavored to put up the very best show South Australia has ever had in the United Kingdom. Our marquee covered an area of 60ft. x 30ft. As it was quite impossible to have a scenic arrangement on the same lines as we have previously had it in the larger halls, I had to adopt a new system. In front of alternate bays we had rows of real flowers, different colors in each bay, thus giving a unique appearance to the whole show. The South Australian exhibit was a success, and proved to be the leading attraction of the section. The following is an extract taken from the *Western Daily Press* of July 5th. This paper is one of the most important outside London, hence my reason for quoting from it in particular:—"The wonders of South Australia, as evidenced in the overseas section, are attracting thousands of visitors daily, there being a continuous stream of interested folk doing the tour of the pavilion wherein the productions of the Central State of the Australian Commonwealth are displayed. In panoramic effect are seen the vineyards, cornfields, sheep farms, &c. Fruits—bottled, dried, and fresh; honey, tinned meats, and such well-known brands of Burgundy as Tintara, Harvest, Emu, Keystone, which are household names, constitute features of the exhibit, which are well known in our own district. The value of such an exhibit cannot be over-estimated as illustrating what the ideal climate and fertile soil of South Australia can produce for the Mother Country in the way of the necessaries and luxuries of life."

On each day there was a continual stream of people passing through the tent from 10 o'clock in the morning until closing time at night. As a medium for advertising South Australia and its products in a general way there is no doubt that this show has been a complete success; but, as I have on several previous occasions stated, I do not consider that agricultural shows, as a rule, are much use to us from a direct trade standpoint. Had I been in a position to do so I am sure I could have sold thousands of pots of honey and any other lines I had that the public could have taken away with them; but, unfortunately, the authorities will not allow selling at the shows.

Amongst the various articles that we exhibited were—Wine, tinned meats, honey, fresh fruit, dried fruit, tomato sauce, and eucalyptus oil.

The panels were executed in oils, and were admitted by the visitors from South Australia to be most realistic of South Australian industries.

In addition to the South Australian Government, the Commonwealth, Western Australia, and Queensland Governments were represented, also the Dominion of South Africa, the Dominion of Canada, the Federated States Settlement, and Bengal Government.

I may say that it was admitted, not only by the visitors, but by the press generally, that the South Australian, though not the largest, was undoubtedly the best arranged and most practical of the whole from a business standpoint.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, August 13th. There were present Mr. G. R. Laffer (Chairman), Professor Perkins, Col. Rowell, Messrs. T. H. Williams (Chief Inspector of Stock), C. J. Valentine, C. J. Tuckwell, C. E. Birks, J. Miller, F. Coleman, A. M. Dawkins, and G. G. Nicholls (Secretary).

Lambs and Sheep.—The following resolution from the Kadina Branch was tabled :—" That in the opinion of this Branch a letter should be forwarded to the Railways Commissioner asking him whether he is prepared to offer any special facilities for trucking lambs and sheep direct to the Port Adelaide works instead of sending them, as now, through the market." The Secretary was instructed to ascertain exactly what facilities were required.

Trade Through the Post.—The Longwood Branch forwarded the following resolution :—" That the Advisory Board be asked to approach the postal authorities with a view to the conveyance through the post, the delivery and the collection of payment for parcels of fruit, cut flowers, certain specified vegetables, and eggs in lots up to 12lbs. weight, and also approach the railway authorities with a view to the carriage of qauntities from 10lbs. upward, at minimum rates, and the advertising at the various railway stations of the names of persons who have fruit to sell." The Branch also desired the Board to " inquire into the facilities available on the lines indicated in our State, in New Zealand, and in England." The Secretary was directed to go into the matter.

Advisory Board Membership.—A resolution was received from the Cowell Conference that, in the opinion of the Conference, branches should have a voice in the election of members of the Advisory Board. It was decided to refer the resolution to the Minister.

Experimental Work.—A communication from the Butler Branch read—" That in the event of the Shannon Experiment Farm not being reopened, the Government be asked to supply each Bureau with seed and manure sufficient to enable one member to conduct experiment plots in each district." Mr. Coleman considered that such plots would serve equally as well as the farm. The Secretary, in reply to a question, said that two men on Eyre Peninsula were now preparing land for experimental work next year and that did not include the proposed operations along the Minnippa Hill railway. It was decided to acquaint the Branch with this fact, and to forward its request to the Director of Agriculture.

Changing a Name.—An application from the Hooper Branch to be permitted to change its name to Wynarka—the name of the railway station—was granted, *New Branches and Members.*—The Board approved of the formation of new Branches of the Bureau at Coonawarra and McNamara Bore, with the following gentlemen as members, viz.:—Coonawarra—Messrs. P. J. Lynch, J. Skinner, T. A. Webber, W. H. Lear, J. N. McBain, H. A. Reschke, E. F. McBain, W. Brown, F. Darwent, L. Stapleton, W. Burkett. McNamara Bore—Messrs. E. Bicknell, G. H. Perriam, W. Hockridge, R. V. Perriam, F. A. Beckmann, J. B. Williams, C. L. Bruce, F. C. Bennier, T. E. Bennier, L. Tonkin, M. V. Blackett, W. W. Paterson, J. D. Aitkin, H. M. Aitkin, F. G. Williams.

The following gentlemen were accepted as members of the Branches shown:—Yongala Vale—G. Keatley; Borrika—C. H. A. Tonkin, J. Wright; Mount Bryan East—E. S. Wilks, W. Campbell; Georgetown—J. Buchan, H. L. Saunders, E. B. Tucker, H. Tucker, W. Mackwood; Berri—J. Wack, V. Fowles; Hawker—W. A. Reid; Redhill—A. Dick; Salisbury—A. R. M. Basford, B. Rumball, F. J. Fleet; Shannon--R. Brown, P. Fitzgerald, H. Schmidt; Pine Forest—E. Hewett; Geranium—W. Morcom, F. Norton, sen., E. Nickols, W. G. Nickols, E. Winch; Millicent—J. B. Mitchell, T. W. Kealy; Blyth—F. Wiltshire, J. H. Pratt, A. D. Pedler; Pinnaroo—J. Pitkin; Hookina—H. Huddleston, F. Stone; Yabmana—F. W. Beinke; Northfield—A. Lowe, J. Eisele; Wirrabara—L. S. Cobiac, H. Francis, W. Rooke; Yongala Vale -J. I'Anson; Elbow Hill—P. C. Wheeler; Hooper—F. Yates, D. Murphy, C. W. Schultz, J. Schultz; Strathalbyn—W. H. Cumming, F. M. Michelmore; Lyndoch—A. Threadgold; Uraidla and Summertown—J. McAskill, F. H. Stacey, G. Collett; Watervale—J. L. Broadbent, F. J. Mutton, J. Ward, sen.; Lameroo—O. W. Davidson, E. F. Davidson, G. A. Martin; Morphett Vale—S. Pocock; Koppio—J. Liddy; Coonalpyn—J. J. Angel, D. T. Cronin; Davenport—G. Goldner; Willowie—A. Bull, A. G. Blight; Renmark—J. E. Smith; Pine Forest—I. Edwards; Paskeville--R. Petherick, A. Petherick; Yallunda—W. E. Rolland, W. Forrest, E. Walsh, W. Winstanley, R. B. Jenkins; Keith—A. V. Shannon, S. C. R. Hantke; Woodside—W. Rollbusch, A. J. McCarthy, H. Howell; Morchard—W. Keauschner; Meningie—L. D. Martin.

Life Membership.—The honor of life membership was conferred upon the following members of Branches:—Messrs. A. F. Noll (Quorn), J. H. Bottrall and J. C. W. Keller (Appila-Yarrowie), M. Eckert (Arden Vale and Wyacca), J. C. Ruwoldt (Mount Gambier), J. H. Knappstein (Clare), J. Brown and W. E. Hargreaves (Port Elliot), C. H. Meyers (Dawson), W. H. Waters (Renmark), D. Hanna and J. Monfries (Gumeracha), J. Binney, R. W. Kleinschmidt, and A. S. Hughes (Willunga), C. W. Fowler, R. W. Salter, A. Friend, and S. Plush (Woodside), J. McKenzie (Minlaton), G. E. Pattingale (Port Broughton), and P. Anderson (Balaklava).

THE WHEAT MARKET.

Under date London, July 25th, *Beerbohm's Corn Trade List* states :—" As will be seen in the following table present indications are for a world's wheat crop about 14 million quarters larger than last year, whilst if this year's crop be harvested in fair to good condition, the amount of millable wheat may exceed last year's by 25 to 30 million quarters. Practically the whole of the anticipated increase is in European countries. The consumption of wheat has been very large during the past twelve months, and of course is steadily increasing each year.

THE WHEAT CROP OF THE WORLD.
(Preliminary Estimate.)
(In Quarters of 480lbs., 000 omitted.)

* Including Bosnia and Herzigovina. † Including Slavonia and Croatia.

In its issue of August 1st the same paper states :—Most of the advices received from America this week are to the effect that winter wheat will prove to be a larger crop than officially estimated on the 1st of July. Both yields and quality are reported to be above the average. Receipts at Western Points are now on a very large scale, so that although the shipments last week were much larger than in the corresponding week last year, *Bradstreet's* " visible " showed a large increase, against a very slight decrease in 1912. Spring wheat, both in the United States and Canada, is progressing satisfactorily, the weather having been very favorable. If the *North-Western Miller's* estimate of a yield of 200 million bushels in the two Dakotas and Minnesota prove correct, the total yield of spring wheat (after allowing for a falling off in the other States at the same rate as for the three principal spring wheat States), would amount to 250 million bushels, against 330 million bushels last year, and would indicate a total yield of winter and spring wheat of 750 million bushels, against 730 million bushels last year.

TO ADVERTISERS.

The "Journal of Agriculture" has a circulation of over 6,500 Copies monthly amongst the Cultivators of the Soil in South Australia, and consequently is a valuable medium for advertising Farm and Orchard Supplies and Requisites.

Particulars as to charges for space on application to the Department of Agriculture, Adelaide.

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on September 1st:—

BUTTER FACTORY.

The beneficial showers experienced last month resulted in a decided increase in the quantity of cream received, the general quality being excellent. Butter is in great demand, but prices eased slightly during the month. Present rates are—superfine, 1s. 2d. per pound; and pure creamery, 1s. per pound.

A. W. Sandford & Co., Limited, report on September 1st—

Butter.—During August supplies of butter and cream increased, and values in butter are therefore somewhat easier than a month ago. Best factory and creamery, fresh in prints, is selling at 1s. 0½d. to 1s. 2½d. per lb.; choice separators and dairies, 10½d. to 1s.; store and collectors', 9½d. to 10½d. per lb.

Eggs.—Rates remained fairly stationary throughout, for, although considerably larger quantities are reaching market, the active demand has readily cleared all parcels offering, local picklers and others being busy putting away for future wants. Guaranteed new-laid hen, 9¾d. per dozen; duck, 10¼d.

Cheese.—The prices that were secured at the beginning of last month attracted importations, and with local supplies showing a substantial increase values have come back equal to export rates, viz., 6d. to 6½d. per lb. for large to loaf.

Honey.—As it is getting late in the season there is only a limited supply left now of prime clear extracted, and orders are not able to be fulfilled at 3d. per lb.; second grade range from 1½d. to 2d. Beeswax is in good request at 1s. 1d. to 1s. 2d.

Almonds are practically cleared at late quotations, with kernels showing an advance of nearly 2d. per lb. Quotations.—Brandis, 5¾d.; mixed soft shells, 5¼d.; hard shells 3d.; kernels, 1s. 5d.

Bacon.—The shortage in the live hog continues, and prices throughout have been high. Best factory-cured sides are selling at 9½d. to 10½d.; cooked hams, 1s.; uncooked 10d. to 10½d.; well cut and cured farm middles and rolls, 7d. to 9d.; country hams, 8d. to 10d.

Live Poultry.—Extremely active sales have ruled throughout the month, no doubt the high price of meat causing a much heavier inquiry for poultry, so that all consignments have been cleared at advancing rates. Good table roosters brought 3s. 6d. to 3s. 10d. each; plump hens and nice-conditioned cockerels, 2s. to 3s.; only a couple of coops of light sorts lower; ducks, 2s. 9d. to 3s. 9d.; geese, 4s. to 4s. 9d.; pigeons, 9¼d.; turkeys from 7d. to 10d. per lb. live weight for medium to prime table birds.

Potatoes and Onions.—The potato market is in a glutted condition owing mainly to the exceptionally heavy yield in Victoria. The demand for Gambiers has been exceedingly small for the time of year, and prices have again eased. Onions.—There has been no difficulty in obtaining adequate supplies of onions, and values are unchanged. Quotations.—Potatoes, £3 15s. per ton on trucks Adelaide or Port; 4s. 6d. to 6s. per cwt. in the market. Onions.—£7 10s. per ton on trucks Adelaide or Port; 8s. to 9s. per cwt. in the market.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

ANNUAL CONFERENCE OF EYRE'S PENINSULA BRANCHES.

COWELL, AUGUST 1st.

The Annual Conference of Branches of the Agricultural Bureau situated on Eyre's Peninsula, was held at the Institute, Cowell, on August 1st. Messrs. F. E. Place, B.V.Sc., M.R.C.V.S. (Veterinary Lectuier), P. H. Suter (Dairy Expert), A. M. Dawkins (Member Advisory Board), and H. J. Finnis represented the Department of Agriculture, and the following delegates were present :—Utera Plains—Messrs. A. Ramsey, J. Norton, M. Hunt, J. Abrook, M. Abrook, G. Hornhardt, A. Venning, W. E. Hier, N. Guidera, W. Gale, E. Sinclair ; Miltalie—T. A. Wilson, P. G. Wilson, J. W. Story, E. Story, J. P. Story, C. E. Scarle ; Elbow Hill—W. T. Cooper, Geo. Wake, A. Wake, S. V. Wake, C. Wake, E. Wake, H. Wheeler, P. Wheeler, C. T. Jacobs, A. Chilman, F. Freeth, G. Dunn, J. F. Brook, A. R. S. Ramsey ; Mangalo—J. H. Cleave, J. W. Deer, J. C. Busch, H. Mackley ; Yabmana—J. N. McCallum, H. McCallum, A. McCallum, G. Story, B. Frost, A. Robertson, J. Robertson ; Roberts and Verran—R. Johnson. A number of visitors also attended.

The chair was occupied by Mr. A. Ramsey, of the Utera Plains Branch, and local arrangements in connection with the Conference were carried out by Mr. T. A. Wilson as secretary to the committee.

CHAIRMAN'S WELCOME TO DELEGATES.

The Chairman (Mr. Ramsey) extended a hearty welcome to the officers of the Department and the visiting delegates. He drew attention to the excellent services rendered the agricultural interests of the State by the ex-Chairman of the Advisory Board, and called on that gentleman to address the gathering.

WHEAT DISEASES.

Mr. A. M. Dawkins expressed his pleasure at being able to attend the Conference, and congratulated the district on the general appearance of the town of Cowell, and the industry and thrift that had been displayed in connection therewith. He did not wish them to understand that he was a scientific man in so far as wheat was concerned, but he addressed them as a practical farmer. Dealing with diseases which affected the wheat plant, he mentioned that red rust was one of the greatest curses with which the farmers had to contend. Frequently it had happened that when the wheat was ripening there would be a monsoonal depression, and a number of red specks on the plants would develop, and increase to red streaks, and instead of a 20-bush. harvest there would be perhaps a return of 3bush. or 4bush. So serious was the position, that in 1884 the Government offered a reward for the discovery of a satisfactory means of dealing with the fungus. Sprayings were advocated without very much success. Dr. Cockburn, in the Legislature, stated that the remedy would have to come from the wheat plant itself. He was aware of the fact that phylloxera, which had wrought such great havoc amongst the vines in France, had been brought into subjection by the introduction of a vine capable of resisting the disease. The woolly aphis of the apple had also been combated by the same method of grafting the trees to blight-proof stocks. Shortly after this Mr. J. Ward discovered amongst his wheat plants a few which seemed to have resisted the rust. These he selected and planted, and in a few years he was able to supply a variety known as Ward's Prolific. It was hard to thrash and yielded a red chaff, and whilst it was satisfactory for growth in some districts, in others the yield was so poor that it would pay to grow other varieties with the risk of their being attacked by the rust. The matter was then taken up by Mr. Marshall, who introduced Marshall's No. 3; and Mr. Farrer, of New South Wales, also undertook the work of crossbreeding and selecting, and he produced some wheats that were immune to the fungus. In the early days, when no artificial manures were used, the period between the time the wheat came out into head and the ripening of the grain was longer than was the case since fertilisers were used. It was at this stage that the rust attacked the plant, and with the shortening of the time during which the wheat was liable to be affected had come less trouble with the disease. In South Australia, to-day, red rust was practically a thing of the past, and he did not think it would ever suppress the yields to the extent it had done years ago.

SMUTS.

There were three other diseases with which he would deal, viz., bunt, loose smut, and flag smut (or black rust). Bunt, or ball, or stinking smut was one of the most injurious diseases that was met with, because it not only destroyed the plant itself, but it would spoil the grain also. When the spores of this fungus came into contact with the wheat grain and adhered to it after sowing they germinated with and entered the young wheat plant, and grew with it, the fungus reproducing itself in the ear, and myriads of spores together forming the familiar bunt ball which took the place of the grain. These spores were capable of germination on most plants in subsequent crops under suitable conditions. The best means of dealing with bunt, loose smut, and black rust was pickling in a solution of bluestone before sowing. He had tried other solutions, but they had not equalled bluestone. Formalin had the advantage that it did not retard germination, but it interfered with the working of the seed through the drill; otherwise it was a very good pickle indeed. The correct strength of bluestone to use was 1 per cent., *i.e.*, 1lb. of bluestone to 10galls. of water. A stronger solution would further retard the germinating power of the wheat, and in some cases destroy it altogether. The wheat should be put out on to the floor, and sufficient solution should be poured on to it to average about 1oz. of bluestone to the bag of wheat. They should remember that each grain of wheat was enclosed in a film of air, and it was essential that the solution should come into contact with the whole surface of every grain. This was effected by turning it over three times on the floor, when three or four bags at a time were being dealt with. It was a decided advantage to do the pickling before seeding was commenced; the wheat dried, and the work was not so rushed. Later sown wheat usually contained more smut than that sown early. When the ground was just damp enough to germinate any smut spores in the ground, but not sufficient to cause the wheat to grow, there was little danger of trouble with the disease, as in the absence of a host plant the fungus died.

TAKEALL.

This had been the cause of considerable trouble during the past two or three years. The crops appeared to be doing well, when a small circle of diseased wheat became noticeable, and this gradually spread. This was caused by a fungus which attacked the wheat plant level with the surface of the ground, worked right round it, and èventually destroyed it. after a hot wind, plants attacked by takeall generally went off much more quickly. There was one way of getting rid of it, and that was by keeping the land absolutely clean when fallowing, and preventing the growth of any grass on which the fungus would thrive, and then by growing oats. In the Wimmera district they found it difficult to deal with spear and barley grasses, and it was there necessary to grow two crops of oats in succession, after which, they could again put in wheat. Oats generally made excellent chaff and there was a good market for the grain, but his experience with this crop was that it was necessary to sow it early, and get the plants above the ground with the first rains. He preferred putting the seed in during April. If the sowing were left until the cold weather came they would not do so well.

DISCUSSIONS AND QUESTIONS.

Mr. A. Ramsey (Utera Plains) desired to know whether it was advisable to pickle wheat on wooden instead of cement floors. Some authorities had recommended the use of 1½lbs. of bluestone to 10galls. of water.

Mr. Dawkins replied that wooden floors and utensils were best, as with iron and cement there was the likelihood of a slight reversion of the bluestone. If iron shovels were used they could be coated with a little boiled oil, which would minimise the reversion. Whilst up to 2 per cent. solution had been recommended, his experience was that 1 per cent. was quite strong enough to kill the fungus, which was all that was necessary.

Mr. Abrook (Utera Plains) had found that wheat put loosely in a bag, dipped in the solution, and well stirred would become uniformly covered.

Mr. J. F. Brooks (Elbow Hill) asked how much wheat could be pickled with 10galls. of solution.

Mr. Dawkins said that so long as the wheat became thoroughly saturated, the aim was effected.

Mr. F. A. Wilson (Miltalie) used about ½gall. of solution to pickle 1bush. of grain.

Mr. W. Cooper (Elbow Hill) used 1lb. of bluestone to 4galls. of water with the floor method of pickling. With this he treated about four bags of wheat.

Mr. Dawkins had seen crops on new land affected by takeall, but he would not advise them to sow oats just on that account for the first year.

Fallowing in New Land.

Mr. J. N. McCallum (Yabmana) read a paper under the heading "Farming in the Franklin Harbor District" as follows:—"In the first place, the holdings in this district in most instances are too large to allow of economic working. Rents, rates, and taxes are being paid on land which is a run and breeding ground for vermin. With land that is being treated for the second or third crop after clearing it is the usual custom to plough or cultivate, and drill the seed in with the straw and shoots still on the ground. It has proved a profitable undertaking to cut, rake, and burn the shoots before ploughing. If there is sufficient straw the fire rake can be used with advantage, but nevertheless I recommend cutting the shoots. Of course, if there is sufficient stubble to burn, all this trouble will be dispensed with. I would strongly recommend fallowing after the third crop, having proved that there is more profit in one fallow crop than two off stubble land. Some farmers put too much under crop in one year in comparison with their working plant. If the effort were concentrated on a smaller area, and better work done on that, there would be a better average for the district. The great drawback in scrub country is the question of feed, and there is room for improvement in the methods adopted for securing this. Thirty pounds of oats drilled in with, say, 30lbs. of super. per acre will generally give good feed by July. On older land on which the shoots and a good part of the stumps have been destroyed, fallowing must be done if we are to be successful. We have at best a light rainfall, and early fallow will materially help to grow a better crop by conserving the moisture. The ploughs should be at work early in June; the end of July should see the work completed. In any case it should not be later than the end of August, in order to allow time for subsequent working. I have proved that that which can be accomplished in districts on the other side of the gulf can be done here by judicious and systematic working. I have at present good feed as the result of drilling 30lbs. of oats and 30lbs. of super. on the stubbles, and a promising wheat crop on early well-worked fallow."

Other Views.

Mr. Abrook (Utera Plains) said the general practice in his district was to put as large an area under crop as they could. Dry-farming methods were not successful; fallowing was not satisfactory. If they secured a small average from a large area that was better to them than a larger return from a small area.

Mr. W. Gale (Utera Plains) believed that fallowing was the best practice. Last year he worked a fallowed area well, and there was a large difference between the crop on that and those on land not fallowed. One difficulty, however, was to keep the land from drifting.

Mr. G. F. Wake (Elbow Hill) agreed with most of the ideas expressed in the paper. Last year he reaped 13bush. per acre from fallowed land and only 5bush. or 6bush. from stubble. Second crops on fallow were in some instances almost as good as first. Holdings in this district were too large in some instances.

Mr. A. Ramsey (Utera Plains) had secured good crops of feed by drilling oats on stubble. One thousand acres was not too much for a good farmer in this district. Last week he went through to Darke's Peak, and in his opinion all the good country would be mopped up by six farms.

Mr. A. Dawkins very much favored small holdings and the work being done well. There was a danger of the farmer undertaking more than he could successfully manage. Rape might well be included when they were sowing oats for feed ; barley also might do well. This was a cereal that finished off more quickly than wheat, and it came in before oats were ready for early feed.

Mr. McCallum, in reply, said he had tried kale with the hay crop. He had a strong working plant, and although the area he held was large, he had it well in hand. He thought it a great mistake to leave shoots on the ground after the crop was put in.

Initial Cost of Farming.

Mr. F. J. Brooks read a paper, from which the following is taken :—" The initial cost of farming must, in my opinion, ever be a fruitful source of controversy. Men start under such diverse circumstances and conditions that, speaking generally, it would be extremely difficult, if not impossible, to arrive at any finality in fixing any sum with which a man could successfully start farming, and although the total arrived at in this paper represents quite a large sum of money for a beginner, I would not for a moment have anyone think that it could not be done for less, or that I would debar any from going upon the land with a smaller amount of capital. On the contrary, I would give the land to every man that asks for it quite irrespective of the amount of capital he may possess. As proving that want of capital is not necessarily a bar to success, I would quote just one instance out of a number which have come under my notice in this district. A man back in the early eighties (when times, by-the-way, were not too good) took up some scrub land under the old credit selection system. After paying the 10 per cent. deposit which was then necessary he had but 4s. 6d. in the world, besides a wife and family. That man, however, succeeded, and a few years ago died, leaving a nice farm, a complete working plant, and a nice little bank balance. Again, others could be quoted who have started with a good plant, a fair amount of capital, and apparently with success assured, and yet have failed utterly. Doubtless, most men here to-day could quote similar instances; therefore, as before stated, I contend that neither capital or the want of it are prime factors in determining the success or failure of the beginner on scrub lands. The qualities, however, which are indispensable are economy, foresight, good management, industry, grit, indifference to hardships and, lastly, luck; for though, generally, luck is not allowed a place in modern farming, I am sure there are many here to-day who will admit that there is a large element of luck in everything pertaining to wheat-growing. Indeed, I know of no other term applicable to the chances which have been known to secure to one man a fair crop, while his neighbor, an equally careful, industrious, and farseeing man may suffer an almost complete failure. What is it but luck which, for instance, prompts one man to choose for seed for the main part of his crop a certain kind of wheat, while his neighbor, acting upon the experience of the past, sows that which has yielded him good returns. The season turns out a 'rusty' one. The first, being rust proof, yields a good crop; the latter, being a non-resisting variety, is a failure. Or, again, a thunderstorm falls upon one man's land and thoroughly soaks it just in the nick of time, securing to him good returns; his neighbor gets scarcely a drop of it and his crop is consequently a failure; and though such cases are of rare occurrence, doubtless every farmer of experience will know of instances similar to those mentioned; and although they have no direct bearing on the initial cost of farming, and so cannot be taken into account, they are still very potent factors in determining the success or failure of a farm started on a given amount of capital, and would lead one man to say, 'Well! I started on such-and-such an amount of capital and have done well.' While the other would say, 'It cannot be done for so much. I started with that amount, farmed well, have been careful in everything, and am in debt.' The nature of the scrub again, whether big or small timber, and the nature and quality of the land, whether hard or soft, must have a direct bearing on the cost of starting a farm. Heavy scrub must, of course, cost more to clear than light; and hard, gritty land must cost considerably more in wear and tear in ploughshares and in strength than soft land. Again, a man's family must be taken into account. He may be a married man with encumbrances, or he may be a married man with a lot of helpers. He may be in close proximity to a good market where he can easily dispose of all he can produce, and where haulage to port or railway station would cost but little, or he may be far back, almost without market at all for by-products, and where haulage to and fro is a very serious item. He may have good feed country where cost of feed would scarcely be taken into account, or he may have land which, until cleared, will grow no feed at all, where cost of feed may be the most serious item he has to consider. Accessibility to water, too, must be a factor in determining the cost of starting a farm. These are a few of the things which must be taken into consideration. From my experience of farming, one never knows what source of expenditure will open out next, so that, as before stated, it is almost impossible to fix upon any given sum with which a man could start a farm with a fair hope of success, except under a given set of circumstances; and as no given circumstances are likely to be applicable, even in 10 cases in a hundred, the figures given herewith can only be taken as a guide in circumstances similar. In the figures appended I am giving what I estimate to be the cost of the indispensable requirements of a man starting a farm in full-going order. I am allowing for a bachelor starting on 1,000 acres of fair average scrub land, not too far from market, but without other advantages such as feed or water, buying everything new, and paying cash for all requirements. It will be found on analyses, that the figures are rather under than over the mark; but the result is, to my mind, certainly somewhat surprising, viz., £899 13s. 4d. The beginning is a very modest one at that. Of course, as before stated, one may commence farming for less; we all know it is often done for less; but under the circumstances given above I cannot see that any less or at any rate any materially less amount would suffice. Appended are the figures referred to, viz.—Six horses at £25 per head, £150; two knockabouts at £10 per head, £20; harness, £28; wagon, £60; six-furrow plough, £40; drill, £40; harrows, £6; stripper, £50; winnower, £25; buggy, £35; horse feed, 20 tons hay at £4, £80; seed wheat for 200 acres, ¾bush. to acre at 10s. per bag, £25; 5 tons super. at £4 10s. per ton, £22 10s.; household requisites, £10; tools and sundries, £10; house, £10; material for fencing, say, 2½ miles, including netting under loan system, about £15; logging and clearing 200 acres scrub at 8s. per acre, £80; wages, fencing, ploughing, harvesting, &c., £45; rent and lease fees, 1,000 acres at 4d. per acre, £18 3s. 4d.; provisions and clothing, &c., £50; contingencies, £50; water conservation, £30—£899 13s. 4d."

Mr. McCallum (Yabmana) thought £800 sufficient for a farm to make a good start.

Mr. Abrook (Utera Plains) said there would be few men growing wheat if they had to wait until they had £800 with which to commence. Some men had started practically with nothing.

Mr. R. Johnston (Roberts and Verran) thought the success of the venture rested as much with the man as with the amount of capital he had at his disposal. A man with grit and experience could start with far less than £800. However, circumstances altered cases. A few years ago it was necessary to pay £40 or £50 per head for horses, but their cost was not nearly so much at present.

Mr. P. G. Wilson (Miltalie) thought the estimate of requirements made by the writer of the paper rather high. A man could start with far less than £800.

Mr. Brooks, in reply, said he did not contend that the amount necessary for a man to start farming was £800. Some men living in retirement at the present time commenced on practically nothing; £899 13s. 4d. was the requirements of a man starting under conditions specified in the paper.

Afternoon Session.

FRUIT AND VEGETABLES FOR THE FARM.

In a paper on this subject, Mr. J. W. Deer (Mangalo) said land intended for fruit trees should be of a deep, loamy nature, somewhat sandy, with a clay subsoil. The site should be well sheltered, and in the hills if possible. A one-way garden plough and a harrow or cultivator would facilitate working. Before planting, all stumps and roots should be grubbed from the land and a good dressing of well-rotted stable manure applied. Ploughing to a depth of 6in. or 8in. should follow this, and the growth of weeds caused by autumn rains should be checked by the cultivator. Holes for the trees should be about 3ft. square and 3ft. deep and 22ft. apart each way, the surface soil being placed in the holes first after the trees were put in. A few rows of vegetables could be placed between the trees, these being supplied with plenty of manure each year. Early varieties of apricots, peaches, plums, figs, apples, pears, and cherries might be tried. Grapevines should be trellised. Almond trees placed 15yds. from the other fruits would make a good break round the garden. From 100 to 150 trees would supply the requirements of the average farmer. When it was intended to grow vegetables commercially the land on which these were planted should be fallowed every second year. Vegetables which did well in this district were early cabbages and cauliflowers, Egyptian turnip-rooted beet, turnips, carrots, parsnips, radish, lettuce, peas, onions, all of which could be planted during April and

May. Cabbages and cauliflowers should be 18in. apart in rows 2ft. apart. For other vegetables the rows should be 2ft. apart, beetroot and lettuce being 1ft. apart in the rows, and others from 3in. to 6in. apart. Potatoes, which paid well in this district, should be 18in. apart in the rows, being buried to a depth of between 4in. and 5in. The best sorts were Pinkeyes, Flourballs, Carmens, and Up-to-Dates ; these should be planted in August and earthed up when about 6in. high. It was not advisable to sow the same vegetable for two years in succession on the one piece of land. Cabbages, cauliflowers, and peas should be followed by root crops.

THE DISCUSSION.

Mr. Alm mentioned that fruit and vegetables did especially well in the hills. He did not favor planting vegetables between fruit trees. From 18ft. to 20ft. was sufficient between the trees. It was a good idea to build a mound of earth in the centre of the hole and place the roots of the tree on and around this.

Mr. Dawkins (Advisory Board) thought the paper a very practical and useful one. On the whole he agreed with the writer, but it was advisable to keep the fruit trees and vegetables in different places; it was a question of moisture. For the first two or three years little harm would be done, but the nourishment that the vegetables took from the ground affected the trees eventually. There was always a danger in connection with working a farm and a garden together, and that was that the farmer might neglect his wheatgrowing. It was always wise for the farmer to have a small garden, but it did not pay to leave the team idle whilst potatoes were being planted.

HOME SURGERY.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) delivered an instructive address on this subject. In dealing with wounds in farm stock he said every attention should be given to cleanliness. It was much better to leave nature to do the cleansing than to put mixtures or disinfectants into the water to be used in the dressing. He explained the method of throwing a beast single handed, and pointed out the uses and principle of the twitch. An excellent embrocation could be made from equal parts of turps and vinegar, ammonia and sweet oil. Probably one of the most successful surgical aids which had been introduced into the veterinary science was the mop with tar. Iodoform was an excellent application for wounds, but the price was high. An equally effective mixture was boracic acid, seven parts, and flowers of sulphur, one part, and it did not carry with it the offensive odor attached to the former. Formalin was an excellent disinfectant, but it hardened up the albumen of the new cells which were forming over the wound and prevented their development. Lysol and such like were good, but their virtues were those of tar, and there was no advantage in their use in preference to this. Medicated oils were good, but their virtues consisted of the iodine they contained. If they purchased a little pure iodine and put enough to lie on a shilling piece into a bottle of methylated spirits, they would have an efficient wet dressing.

MAKESHIFT APPLICATIONS.

Vinegar and water constituted a very good temporary dressing. Turpentine was equally good. Salt and pepper also were excellent first-aid dressings. When joint oil was running, ordinary washing soda was not to be despised. Washing soda and Condy's crystals would be found excellent dressings for large wounds. In 99 cases out of 100 it was not necessary to worry about a horse losing a lot of blood. All animals fainted when they lost too much blood, and as a result bleeding stopped. When an animal bled to death it generally expired within a few minutes. If blood were squirting from an artery, pressure would stop it. Very hot water applied to wounds bleeding badly would kill any germs, and at the same time encourage the rapid formation of the blood clot.

The class of wounds generally found in this and similar country consisted of trouble caused by stakes, stubs, barbed wire, &c. With regard to stubs in the feet, if they spent five minutes opening out the wound and then poured in a little turps, it would be found that the lameness would disappear in far less time. The ordinary paddock of green feed was a fairly antiseptic place in which to put the patients. A strand of fencing wire made a good probe, and with this one could tell whether any foreign body was inside. A 5 per cent. solution of cocaine applied to the skin around the wound, after it had been scratched with a knife, would assist in controlling the movement of the animal whilst probing or opening out was being done. If an animal had a running wound about the legs the owner could do no harm by endeavoring to find some foreign body.

BARBED WIRE.

Cuts due to barbed wire were best dealt with by first being thoroughly washed. Water should then be kept away from the wound until it healed, or proud flesh was likely to result. Iodine made an excellent dressing. In the majority of cases it was not advisable to sew up the wounds, but if it were so, a bag and not a sewing needle should be used. The general result, however, was to sew in dirty matter, which resulted in the swelling of the part and the breaking of the stitches. The simplest means of preventing the animal biting itself was by the use of a cradle, consisting of a number of rods or sticks extending from its head to its shoulder along the neck. This should be tied to the mane at the top and the bottom. It was necessary to keep an eye on the beast, to see that its general health was good.

QUESTIONS.

In reply to questions, Mr. Place said "Law's Farmers' Veterinary Adviser" was a publication that was well suited to the requirements of the farmer. The best method to stop the bleeding in the case of a colt which had been castrated was to plug the purse with cotton wool or tow with an antiseptic. It would probably continue to drip for some two or three hours. When, however, there was a regular pumping squirt of blood, hot water should be applied over the loins. The knife was better than the searing iron for tailing lambs, as there was less danger from lockjaw. When the bleeding appeared too severe, the application of bluestone would be found satisfactory.

SHEEP AND GRAIN.

Mr. W. L. Brown (Yadnarie) read a paper as follows:—"Every farmer should combine sheep-raising with grain-growing. The first point he has to look to is the carrying capacity of the farm. On no account should he overstock. He should then decide whether mutton or a class of sheep that will grow the most valuable fleece (which I believe is the Merino) is to be his objective. If he thinks a large-framed sheep for mutton will pay him best he should breed one of the long wool crosses, such as the Lincoln-Merino. They are large-framed and good doers, and the lambs mature earlier than the Merino. Wool of this class for several years has been highly favored by wool-buyers. The Merino is the best breeding ewe; the larger the frame the better. They should be mated with a Lincoln ram, which should be well-grown, bold, masculine-looking, robust, and vigorous. The only disadvantage with this cross is that they are troublesome with the fences; but paddocks netted with 4in. x 4in. x 2ft. 6in. sheep netting will be found most effective and as cheap as a six-wire fence. In this district I prefer the lambs to come in June, as the rains are sometimes late, and with them the feed, which makes but slow headway at any time until June or July. As we have not a market for lambs it is not necessary to study that industry at present. Sheep are a great help to the farmer. In the first place they provide meat, which is a very great saving. They also assist in keeping his fallow clean. Sheep as improvers of the soil cannot be too highly esteemed. A sandy stubble paddock on which sheep are turned will retain moisture almost as well as fallow, as the top is kept loosened. With regard to the drafting yards, it is preferable to make these of posts or stakes about 3ft. high, standing perpendicularly and close together, as the sheep neither see through nor get hung up in them. The yard should be on the slope, so that no water lies about in wet weather. The design depends upon the number of sheep kept. When shearing time comes the farmer should provide a cool, well-ventilated but not draughty shed adjoining his drafting yards. At least enough sheep to provide a half-day's work should be under cover in advance, so that the shearers can start at the proper time and are not kept idle, as is often the case owing to the heavy dews we invariably have at that time of the year. The sheep under cover should stand on grating made of timbers set ¾in. apart. This will allow all mud or straw that comes in from the outside yard to fall though, and thus the wool will be cleaner. The get-up of the clip is most important. If a farmer has a large number of bales the fleeces should be skirted, and the skirtings, locks, and bellies put into separate bales. Where there are only 50 or so sheep kept, all that is necessary is to skirt the fleeces of all wet and stained wool. This can be put in with the locks. A small sheepfarmer does not gain by having a large number of parcels. After the bales have been sewn, if the number of the bale, the kind of wool, and the brand are neatly printed on, instead of being scratched on anyhow, it will look nicer and attract attention. Six weeks after shearing the sheep should be dipped. The farmer will then find that his sheep will be free from tick and the fleeces will be in better condition."

Mr. Robertson (Yabmana) and Mr. Abrook (Utera Plains) agreed with the remarks of the writer of the paper.

Mr. W. E. Hier (Utera Plains) thought farmers were well advised to go in for sheep in this district. He favored the Merino crossed with the Shropshire.

Mr. Wheeler (Elbow Hill) thought it a mistake to have lambs coming in March or April. If they were dropped later in the year, say in the spring, the ewes would have a better chance of caring for the lambs, as there was good feed available. Overstocking was to be guarded against.

FREE PARLIAMENT.

THE ADVISORY BOARD OF AGRICULTURE.

At the instance of Mr. T. A. Wilson (Miltalie), seconded by Mr. R. Robertson (Roberts and Verran), the following resolution was carried :—" That this Conference is of the opinion that Branches should have a voice in the election of members of the Advisory Board of Agriculture."

NEXT CONFERENCE.

It was decided that the next Conference should be held at Cleve, the Roberts and Verran Branch undertaking the arrangements.

Evening Session.

PLOUGH OR CULTIVATOR.

The following paper was read by Mr. I. R. Hill, of the Miltalie Branch :—" The preparation of the soil for seeding means the renovation of the land for the growth of corn and other exhaustive crops. This involves freeing the land from weeds and the restoration of its fertility by atmospheric agencies as well as direct manuring. There are various implements for working the fallow and preparing the land for seeding. Up to the present time in this district very little preparation has been done; in fact, the only implement used is the plough. In many cases the same implement is used for ploughing and working the fallow. The farmer who wishes to reap a good harvest must prepare the soil for the reception of the seed, as he now prepares his seed for the soil, knowing full well that it is the land that has received the best preparation that is the most reliable in good or bad seasons. The work should begin the year prior to that in which the seed is sown. Farmers hold different views as to the most suitable way to work their fallow land after it has been ploughed. Some contend that the better way is to go over the soil with the skim plough, and turn all weeds under. This does not commend itself to me. It may be advantageous to plough back the fallow in the very wet districts, but in a district such as ours, where the moisture in the soil should be jealously guarded, farmers will find that the use of the cultivator and harrows will be far more profitable. As to the quantity of rain needed for the production of a payable crop, some valuable information has been gathered during the (1911) harvest from results obtained on experimental plots in the southern districts of New South Wales. Generally farmers contend that from 10in. to 12in. are essential during the growing season. That good crops can be grown with a far less rainfall than that has been clearly demonstrated. At Wyalong the total rainfall from the time the seed was sown until the crop was harvested was 6·68in. The average yield from a 10-acre plot was 24bush. per acre. At Jindera (Albury), with a rainfall of 7·52in., an average yield of 22½bush. was obtained, and Federation returned as high as 28bush. 56lbs. per acre. More remarkable still are the results from the Deniliquin plots, which were sown on May 1st and 2nd. In this case the total rainfall amounted to only 3·22in.—a yield of 14bush. per acre resulted. In each of these instances the land was fallowed and worked with the cultivator and harrows to leave a loose, dry mulch on the surface. A large amount of the previous year's rainfall was thus stored and conserved in the soil; so practically the fall of two years was employed in the production of one crop. Surely such results should leave no further doubt in any farmer's mind as to the necessity for thoroughly working his fallow land."

DISCUSSION.

Mr. W. E. Hier (Utera Plains) thought the plough should be followed by the cultivation of the surface of the land. The use of the plough again for this purpose would result in the loss of moisture, but the use of the scarifier had an opposite effect. The skim plough was very suitable for ploughing in weeds, but on land that was inclined to drift, a tyne implement was better.

Mr. Abrook (Utera Plains) said that if the principles recommended by the writer were applied in his locality there was every likelihood of the land blowing away. Land of this nature was better ploughed and left rough.

Mr. Alm was well satisfied with the work being done by the cultivator on the fallow.

Mr. G. Storey (Yabmana) preferred harrowing the ground after ploughing, and then using the cultivator if thought desirable. If they fallowed early, cultivation would be necessary two or three times to kill the roots. As a result the land became very hard, and in some instances another ploughing would be necessary.

DAIRYING.

The Government Dairy Expert (Mr. P. H. Suter) delivered an interesting and instructive address on "Different Phases of the Dairying Industry," illustrating his remarks with lantern slides.

* * *

CONFERENCE OF PINNAROO DISTRICT.

The Annual Conference of Branches of Agricultural Bureau situated in the Pinnaroo district was held at the Institute, Pinnaroo, on August 14th. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), Professor Perkins (Principal of the Agricultural College, Roseworthy), Messrs. Colebatch, B.Sc., M.R.C.V.S. (Superintendent of Agriculture in the South-East), F. E. Place, B.Sc., M.R.C.V.S. (Government Veterinary Lecturer), D. F. Laurie (Poultry Expert), G. R. Laffer (Chairman), F. Coleman, C. E. Birks, and G. G. Nicholls (Secretary Advisory Board), attended, in addition to the following delegates :—Parilla—H. E. Johnson, A. J. Stevens, M. Shannon, and C. Millstead ; Lameroo—E. J. Trowbridge, E. T. Wray, F. W. Eime, and A. J. A. Koch ; Clanfield—A. Correll, P. Nelson, and H. Milne ; Claypan Bore—J. Gray, E. Colwill, and F. S. Tall ; Parrakie—F. J. Dayman, R. E. Jose, R. L. Beddome, and M. J. Cooney ; Geranium—W. Mitchell and R. Jacob ; Hooper—J. R. Beck ; Borrika—J. H. Gray ; Wilkawatt—D. F. and W. J. Bowman, J. Ivett, and W. J. Tylor ; Parilla Well—J. W. Johnston, J. Ferguson, A. Webster, A. Foreman, and L. G. Neville (Assistant Hon. Sec.) ; Pinnaroo—F. H. Edwards, H. Ledger, J. Scales, E. H. Parsons, P. J. Edwards (Chairman), P. H. Jones (Hon. Sec.).

A large number of Bureau members and visitors also attended each session.

The Chairman (Mr. P. J. Edwards) extended a hearty welcome to delegates and visitors. He expressed appreciation that the Hon. Minister had found time to leave the stress of Parliamentary duties, to attend and open the Conference, and called on him to address the gathering.

MINISTER'S OPENING ADDRESS.

The Hon. T. Pascoe expressed great pleasure at being present. Such gatherings as this constituted some of the purple patches in Ministerial experience. It was especially pleasing to him to attend the Agricultural Conferences, because, after all, he was more of a farmer than a politician, and his sympathy went out to the farming community above all others. They fully recognised the value of their industry to the State, and how much the country was dependent upon it. It was a curious fact that people in the city apparently felt the effects of hard times much more quickly and acutely than the agriculturists themselves. He believed that this season the more recently settled districts, such as this, were really better off than those north of Adelaide, generally regarded as absolutely safe. Except in one or two very favored places in the latter areas they would not find anything like the feed and crops indicated by the samples exhibited that morning. The fact that the mallee districts were not so badly off as many others was particularly gratifying, because in them so much depended upon the first two or three seasons. If these should prove to be poor, there was a great danger of throwing the country back probably for years, and disheartening the new settlers. Perhaps the most stimulating features of the Pinnaroo and Brown's Well country were the enthusiasm and the energy which the farmers were putting into the Agricultural Bureau, and the fact that they were willing to teach and learn from each other. Altogether there were 15 Branches in those localities, and they comprised 400 members, who were anxious to bring the latest scientific knowledge to bear upon their work. With such a large percentage of settlers of that calibre, who could but help feeling that absolute success must attend the agricultural industry in the new country.

1889 AND 1912.

It was highly encouraging to review the growth of the primary industries in South Australia as revealed by the statistics for the years 1889 and 1912. In the former the average rainfall over the State was 25·29in. (one of the highest totals on record), and in the latter only 14·39in. (one of the lowest). The area under cereals in 1889 was 2,246,510 acres, and in 1912, 3,001,723, and the areas under bare fallow 591,432 and 1,537,789 acres respectively. Those figures presented striking contrasts. Although the increase in the area under cultivation was not very marked, the fallows showed that there had been a great advance in the nature of the farming. Put in another way, the percentage of bare fallow to the total area cropped had increased from 26·3 to 59·6. He was convinced that in the mallee country the area fallowed each year would advance as the farms were cleared and properly improved. In 1889 the wheat produced amounted to 14,577,358bush., or an average of 7·91, compared with 21,496,216bush. and an average of 10·34 in 1912. Could they desire any stronger evidence than that of the benefits to be derived from and advantages of good agriculture ? In the same period the area devoted to orchards and vineyards had advanced from 26,935 to 61,149 acres, and the quantity of wine manufactured from 762,776galls. to 3,974,838galls. From the figures he had quoted it was obvious that they were making their land yield better results than in the past, even in the seasons of reduced rainfall. That was a fact upon which they might well congratulate themselves, because it strengthened their hopes for the future of the primary industries of the State. Having apologised for the absence of the Director of Agriculture (Professor Lowrie), whose ill health prevented him from leaving his home, and mentioned that he had asked Mr. Colebatch to attend the Conference in his stead, the Minister paid a powerful tribute to the valuable influence of the Agricultural Bureau, and to the officers of his department. He was exceedingly proud of the ability of his experts. The six of them (Professors Lowrie and Perkins, Messrs. Colebatch, Laurie, Quinn, and Place) were on the top rung of the ladder in their particular lines, and he did not think half a dozen men of equal merit could be found in any Agricultural Department in any other State. All the officers were working earnestly, honestly, and harmoniously together with him for the welfare of the State. In conclusion, he declared the Conference open, wished it every success, and hoped it would be merely the forerunner of many others.

STAKED AND FISTULOUS WOUNDS.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.;) delivered an address on this subject, in which he said wounds of this nature were generally found in positions where they were likely to cause lameness for a considerable time, such as on the sole and frog, or above the hoof-head, where the ligaments were tender and thick. Fistulous wounds also occurred in parts of the body where the vitality was low or less active than it was in fleshy situations. When a semi-blunt stake penetrated, it almost invariably carried in some outside matter, or some part of the horn, hair, or skin was introduced, thus providing an excellent medium in which germs could breed. The difficulty with wounds in the lower parts of the foot was that they became choked with the dirty matter, and if not treated in the early stages, in a few days developed a running sore, which filled the horny base of the foot. The leg began to swell, and the horse was in danger of death through blood-poisoning. With fistulous wither the damage was done under the skin. Rolling on a stone or mallee root usually caused the trouble. The first symptoms, perhaps, were a flinching or tenderness, but soon a swelling occurred. This continued, and very likely increased, until it was found that the hair disappeared and there was a deadening of the skin, and a breaking out with a flow of matter. What was wanted was drainage at the bottom of the wound. Fistula was not a sort of cancerous growth, but a wound which consisted of pipes that were brought about by the growth and action of germs that were in the wound. After these had destroyed part of the bones in the wither they attacked the muscles lower down. A probe should be pushed gently down these tubes. Burning with spirits of salts and oil of vitriol had been recommended by old writers, and in some cases this treatment had resulted in healing, but in others the oil of vitriol had caused the death of the animals. The best method was to restrain the horse, and open out the pipes which were traced by the probe. There was no need to trouble because a fair amount of blood was lost. The wound could be swabbed with the cotton wool or clean rag. The constant application of water softened the tissue, and enabled the live cells to grow quickly and heal the wound; therefore it was well to flush the wound well with cold water. The hose or some other similar method could be used to irrigate the wound for an hour or so per day. If they preferred drugs they could use them, although they were not necessary. Whenever possible it was advisable to keep the animal at work; otherwise the muscles became stiff, and the blood was not kept so clear. With stubs on the bottom of the foot it was best to make an opening large enough to prevent the wound healing too quickly. A popular treatment was to apply a mixture of cowdung and Stockholm tar. It softened the horn, and would draw well, which, in other words, simply meant an increase of the activity of the germs near the surface, so that instead of burrowing into the hard tissue they increased so fast that they had to come away as matter. If the wound were near the hoof-head, it was necessary to see that no foreign matter was in it. When the stub ran inwards towards the hoof it would often be found that the wound healed very quickly, but a month or so afterwards lameness became very marked, there would be a swelling, and perhaps a breaking out at the heels. If by neglect they got a condition of this kind they had better make an opening low down, because the trouble was burrowing between the bone of the foot and the hard horn on the outside. They could materially reduce the pressure where the horn was in contact with the tender parts by rasping it down until it was very thin. One point that must not be lost sight of was that if the operator removed part of the hoof-head that was responsible for the formation of the new horn he would cause false quarter. To obviate this he should not cut through the horn-head, but cut through the horn.

QUESTIONS.

Mr. J. B. Beck (Hooper) asked what, in the event of it being necessary to draw the matter from the wound, the lecturer would recommend for a poultice.

Mr. Place replied that anything that could be used in quantities was useful. Bran was very frequently recommended. Bread, turnips, &c., when boiled made good material. For drawing the foot, Stockholm tar was better than anything. The chief point to remember was to have an abundance of poulticing material and keep that constantly hot and wet. This was best done by pouring water, at not too high a temperature, on to the poultice from time to time. If the animal could be made to stand in hot water for a while, and if they happened to have a piece of old felt which could be put on the foot, this would be better than poulticing.

SANDY LAND.

Mr. R. Jacob (Geranium) introduced a discussion on the subject of "Sandy Land and its Cultivation." On account of the coarseness of soil particles, he said, sandy land was somewhat weak in capillarity, and was unable to carry as much moisture in suspension as was the case with heavier lands, properly tilled. There was free percolation of moisture downward, and free æration of the soil to be considered in determining the best methods of cultivation. It was a serious mistake to work sandy land in a dry state. It should be worked wet in order to consolidate the soil, form a good seed bed, and improve the moisture-retaining powers. He had found the harrows the best means of packing the soil, while much good would be done by running stock on the land. A feature of sandy land was the lack of humus, which reduced the moisture-retaining capacity. There was also generally a weakness in lime. He ploughed such land fairly deeply for a start, and then packed it thoroughly with the harrows. The aim should be to avoid over-cultivation, at the same time securing a maximum moisture-retaining capacity, the introduction of humus, and addition of lime and stronger fertilisers. Stable manure could not be obtained in sufficient quantities for the treatment of large areas, but was admirable for increasing the supply of humus. Ploughing in green crops was a practical way of making the addition, and the same purpose could be served by feeding down fodders on the land with stock and subsequently ploughing in the droppings of the animals. The Pinnaroo district was fortunate in possessing a clay subsoil close to the surface, and this enabled them to grow a diversity of fodders for green manuring.

Mr. Ledger (Pinnaroo) said the sandy land this season was growing luxuriant crops. His experience was that sand in wet seasons held too much moisture and gave poorer returns compared with drier years. The drifting of the sand was not a serious problem, although objectionable near the homestead. Humus could be added to the soil by ploughing in the straw from the crops. He advised farmers to plough and fallow their sandhills from the first. If there were to be slipshod farming while getting a start, that should be applied to the flats in preference to the sandhills.

Mr. Colebatch said there was a reasonable explanation for sandy soil at Pinnaroo giving better yields in dry seasons than in wet ones. The capillarity was weaker, but the moisture was readily available when the plants most required it. In wet years the fertilisers in the soil had a tendency to leach beyond the reach of the plant roots. When fallowing in June he believed in deep ploughing, providing the soil was firmed up afterwards. In spring ploughing, 3in. ploughing was ample, or a lot of work would be required in consolidating the land for wheat. For firming sandy land the harrows were effective.

Mr. Birks (Advisory Board) related his experiences in the Wandearah district, where the working of sandhills had in some instances set up serious drifts. Some men had left the tops of sandhills untouched when fallowing and had got good yields. Growing fodder crops and feeding off lightly with stock was preferable.

Mr. Tyler (Wilkawatt) had fallowed land at the end of May 4in. deep, and had harrowed in melilotus seed, scattered broadcast. He intended to feed the fodder down and cultivate the remainder in about October.

Mr. L. McCormack (Pinnaroo) considered it a mistake to fallow sandhills at all, and it was bad policy to allow them to remain bare. He suggested growing something on them, and feeding off about March.

Mr. Parsons contended that there was very little sand in the hundred of Pinnaroo, even on the largest hills. Rarely did it exceed a foot, and generally it was only a few inches deep.

Mr. F. Norton (Geranium) believed in growing fodders for stock. He had tried peas, lucerne, and English grasses, which had improved the land for wheat-growing purposes. He referred to the merits of peas, rape, millet, sorghum, and maize, and said that by attention to fodder cultivation, five or six sheep to the acre could be kept and fattened profitably, and at the same time humus added to the soil, and fertility enhanced. They had to grow wheat until they got the land cleared of the mallee, but there was a bigger thing in stock-feeding than was commonly realised. In sowing seeds of English grasses a light rolling afterwards greatly increased the germination percentage.

Mr. Troubridge (Lameroo) said some of the most promising crops were on sandy land that had been fallowed.

Mr. Johnson (Parilla Well) claimed that fallow was not a cause of serious drifting if the land was not worked too much before the summer was over.

Mr. Koch (Lameroo) had found it beneficial after fallowing to cultivate north and south when necessary after rains, so that the ridgings prevented undue drifting over the heavier soil on the flats.

Afternoon Session.

IMPROVEMENT OF STUBBLES.

The Superintendent of Agriculture in the South-East (Mr. W. J. Colebatch, B.Sc., M.R.C.V.S.) delivered an address as follows :—"Both wheat and sheep farmers, and those engaged in pioneer farming in the mallee scrub districts, will recognise the importance of giving some thought to the subject of stubble improvement. The wheat and sheep farmers on ordinary arable holdings will be chiefly interested in that phase of the subject that concerns the production of an increased amount of good sheep feed, whilst the scrub pioneers will be inclined to devote more attention to stubble improvement as a means of increasing the amount of straw and flag with the object of ensuring a good burn.

"However, it will only be during the process of reclamation that settlers in the light sandy mallee areas will view the matter from this point. When once the shoots and roots have been destroyed and the land has been brought under a suitable cropping rotation, they likewise will come to value their stubbles as a source of humus, and as a serviceable protection to the natural and self-sown growth of autumn green feed. Still, at the commencement, they are confronted with a real difficulty when unable to secure a satisfactory stubble burn, for it has come to be recognised that inability to destroy the shoots and roots by means of stubble fires during the first few seasons may mean all the difference between prosperous and unsuccessful settlement. Indeed, so important has the problem become in these districts that the selection of the crop to be grown is often determined by its capacity to yield a good heavy stubble. Nor does it appear that the difficulty may be attributed to faulty methods of cultivation and manuring.

"The experience of farmers who have coped with the difficulty and have successfully cleared their blocks is found to vary according to the nature of the land they have had to work. Those who have been fortunate in the selection of their blocks have had very little difficulty in raising wheat crops thick enough in the plant to carry fire, and they naturally advocate the continued growth of wheat for two or three seasons as the best means of subduing the scrub. Others again, who have been less successful with wheat, advise sowing oats after the first crop, and then bare fallowing. On some of the poorer blocks, however, even oats have been found to fail as a stubble-producing crop, and it has been found necessary to fallow up after the first crop in order to obtain the purpose in view. Under such varying soil and climatic conditions no definite rules can be framed. The best practice must be worked out in each district, and each new settler will do well to profit by the experience of those working under similar circumstances. It cannot be gainsaid, however, that under these necessitous conditions every effort should be made to secure only clean graded seed and manure of the best quality, and to endeavor to get the crop sown well and in good time. Where the rainfall is fairly well assured, as it is on some of the settlements in the desert, I think oats should be preferred to wheat where stubble is a desideratum. They produce a large amount of straw and flag, which burns readily, and, furthermore, they can be sown earlier than wheat without undue risk, provided they be well covered. If sown towards the end of April they will be ready to respond to the first showers, which is a distinct advantage, particularly where stem and leaf are specially sought after. In a late autumn, such as we have just experienced, the opportunity for dry sowing is almost sure to have been availed of; but when it has been allowed to slip past and oats have to be drilled after the wheat is all sown, I think it would be wise to try Cape instead of the Algerian variety. They make better growth in the cold weather, and take less time to mature.

"On the inferior soils in the more humid localities I would suggest rye as a crop likely to develop a good burnable stubble. Of all the cereals it is the one best adapted to poor land, and though the grain yield is inclined to be low, it rarely fails to provide a good supply of straw. The straw is barer of flag and stiffer than oaten, but I have never experienced any difficulty in burning it off.

"In districts where the annual rainfall is 18in. or thereabouts, and where the soil is too poor to produce good stubble, an improvement might be effected by sowing a bushel and a half of field peas per acre on the fallow, the early Dun variety, drilled in pairs of rows with 70lbs. to 100lbs. of standard mineral superphosphate per acre. I find it better to drill in pairs of rows on light land, as this arrangement allows each row additional space to spread over, as well as a more extensive feeding area. If the land has been fallowed in June, it should be let lie in the furrow till the worst of the winter frosts are over, which will usually be about the end of July. Peas are found to do best on an old furrow, and for that reason are commonly sown on the earliest piece of fallow available. The harrows should follow the drill to give a good cover, and the field may then be left till the crop is ready to be fed off. The success that we have had with peas at Kybybolite on poor sandy, sorrel-infested soils makes me think it likely that they would suit some of our mallee scrub farms. They favor light open soils containing plenty of lime, and are fairly hardy provided they are not asked to withstand prolonged winter frosts during the early stages. That they will ultimately find a place in the regular rotation practised over our light lands south of the Murray I have little doubt. On sandy soils under relatively heavy rainfall the nitrates are rapidly washed down into the deeper layers, and I know of no better means of replenishing the land than by periodically cropping it with pease or lucerne. It would be foolish to anticipate any decided improvement in the stubble feed until the wheat-cropping system is made to give place to a rotation that includes one or other or both of these legumes. Their action as nitrogen collectors on the nitrification processes in the soil has been closely studied by Messrs. Lyon and Bizzel at Cornell University. These observers have shown by experiments that, in addition to restoring to the soil a quantity of nitrogen compounds which are available later for other crops, the growth of legumes may also furnish nitrogenous food to other plants growing with them and then influence the nitrification of the soil besides.

"The following table shows the influence of lucerne, peas, and red clover on crops growing up with them :—

Grain Grown Alone.		Grain Grown with Legume.	
Grain.	Percentage of Protein.	Grain.	Percentage of Protein.
Timothy grass	12·75	Lucerne	15·56
Timothy grass	17·19	Red clover	24·56
Oats	11·23	Peas	12·71

"The yield as well as the quality has been shown to improve as the result of association with legumes. In the experiment with oats sown alone and oats sown with peas it was found that the yields on duplicate plots were as under—

Pounds of Hay per Acre.

	Oats Alone.	Oats and Peas.
Plot 1	2,900	3,900
Plot 2	3,750	4,850

"A further series of tables might be prepared from these results to indicate the total increase of proteins per ton of yield, for it is evident from the foregoing that the hay produced on the mixed plot was of greater food value weight for weight. The effect of legumes in increasing nitrification in soils was tested as follows :—The percentage of nitrates in soils that had borne legumes and in those that had not done so was first ascertained. A known quantity of nitrifiable material was then added and the soils were further tested for nitrates at intervals. The rate of nitrification was found to be higher in the infected soils.

"These results are peculiarly interesting to farmers on inferior land, as they enable us to understand how we may best control the nitrogen contents of our soils in districts that must of necessity be burnt off for several successive seasons. In order to help us to a clear understanding of the position it is as well to refresh our memories in regard to the fertilising value of the residual ashes. The following table indicates the percentage of potash, phosphoric acid, and lime in the more important kinds of ash met with on our burnt stubbles—

	Potash.	Phosphoric Acid.	Lime.
Wheat straw	12·16	3·20	6·82
Barley straw	19·32	4·83	7·00
Oat straw	20·60	4·16	8·10
Rye straw	17·36	3·82	9·06
Pea straw	22·00	6·84	39·00
Bean straw	21·26	7·35	21·29
Mallee wood	2·42	·48	40·90
Mallee roots and tops	1·80	·41	44·94
Red gum	5·20	3·20	35·98

"It will be noticed in the first place that all the nitrogen has disappeared during combustion, and that the different ashes vary widely in composition. The cereal stubble ash is several times richer in potash and phosphoric acid than the mallee ash, but the latter contains roughly about five times as much lime. Peas yield practically as much lime in the ash as mallee or red gum, and they are richer in the other two minerals.

"Under the present system of farming that settlers are in most cases compelled by force of circumstances to practise there is a steady drain on the nitrogenous contents of the land as well as the mineral constituents. Where no sheep are kept and ordinary superphosphate is used not an atom of nitrogen is intentionally returned to the land. On the stronger types of soil nitrification may suffice for a number of years to meet the demands of crops, but on the sandy land, which is more liable to suffer from leaching, I cannot but think that a radical change in farm practice will soon be forced upon us. The steady depletion of the soil's store of nitrogen will have to be made good again, and this, I believe, will be most economically accomplished by growing peas on the fallows, sowing lucerne with the crop in the autumn, broadcasting forage crops on the growing cereals at the end of the winter, the establishment of stands of lucerne, and the cultivation of spring-sown fodder plants.

"The ultimate effect of growing forage for sheep and of grazing off the stubbles will be to strengthen the land, sweeten it, make it more retentive of useful moisture, improve the character of the stubble feed, and generally increase the agricultural value of the holdings. The following table of Lawes and Gilbert shows what a small percentage of the fertilising ingredients contained in the food consumed is retained by fattening stock.

Percentage of Nitrogen and Ash Constituents Voided by Livestock.

	Nitrogen.	Minerals.
Fattening cattle	96·1	97·7
" sheep	95·7	96·2
" pigs	85·3	96·0
Milking cows	75·5	89·7
Calf fed on milk	30·7	45·7

"These figures go to show that less than 5 per cent. of the important fertilising ingredients consumed by sheep are absorbed during the period of fattening, the balance being returned to the land in the form of manure. This is a most important fact, and one that should never be lost sight of. On it is based the whole theory of soil improvement through the agency of livestock. The greatest need to-day on all our light mallee soils is organic matter, and in order to make good this deficiency and to commence the task of building up the reserves of fertility, settlers should endeavor to commence growing feed and running a few sheep at the earliest opportunity.

"The ploughing and working of the land in the ordinary course of cereal cropping will lead to its amelioration and tend to improve the natural growth of feed up to a certain point, but no permanent advancement will be made without resort to mixed farming in some form or another. The particular system adopted will, of course, vary with the conditions. What will pay best on the good land at Pinnaroo will probably not be so suitable on some of the light sandy country farther south.

"The cultivation of peas on the fallows has already been referred to at some length, and the practice of sowing 3lbs. or 4lbs. of lucerne seed with the crop at seeding time is thoroughly well understood. It is not always possible to augment the stubble feed to any extent by this means, and in a dry year very little benefit may result from it, but the farther south it is tried the greater the chance of success, and when favorable conditions ensue the improvement is very striking. The broadcasting of French cabbage or chou moellier on the growing crop when it is about 6in. or 8in. high has been tried with considerable success by Mr. S. Schinckel, of the Naracoorte Agricultural Bureau, and a number of others are adopting the same practice. It has been tried with oats, barley, and wheat, but the last-mentioned appears to be the most suitable nurse crop. The system followed is to broadcast about ½lb. of seed mixed with sawdust, or some other such vehicle, and then run over the land with the harrows.

"The laying down of a few acres to lucerne each year near the homestead will help to a conclusion as to the advisability of attempting to seed larger areas with this useful fodder. Where the preliminary experience has been encouraging, steps should be taken to fallow a block of land in preparation for next year. It is better not to make use of a nurse crop even when sown in the autumn. If the season is favorable, and it can be sown safely in April, it will have a chance to get established before the frosts set in, but this is generally such a busy time that the work is apt to be hurried through, and it is therefore better, as a rule, to wait till the frosts are past and get it sown at the end of July or early in August. Drill in from 5lbs. to 8lbs. of seed and 1cwt. of super., and cover lightly by using a brush harrow. Harrow it at the end of the spring, and stock it lightly the first summer. At the end of the winter give it another harrowing, or, if the land will stand it, run over it with the double disc. The crop should then be firmly rooted, and if given a cultivation or harrowing from time to time, and kept well manured, it should give a good account of itself for a number of years.

"The cultivation of spring-sown fodder crops does not necessarily imply the use of the Planet-Jun. during the summer, though a larger measure of success will usually be attained if the crop is horse-hoed at or about the time when the rows become well defined. In our experience at Kybybolite very much better results have been obtained with thousand-headed kale than with either rape or chou moellier. The former suffers severely from aphis and caterpillars, and the latter appears to be much slower in development after being once fed down. Every district, however, should investigate the respective merits of these fodder crops for itself, and having determined them, should use the most suitable as a means of adding humus to the soil and increasing the stock-fattening capacity of the land."

At the close of the address numerous questions were asked and replied to by the lecturer, who said that rape and thousand-headed kale, if they could be grown, would be excellent for them to try. Chou moellier did not recover so well as kale after feeding off, as the sheep would be found to attack the sweet, succulent stem. In moist land they should not incur any danger in mixing the chou moellier with super. At Kybybolite it was sown in rows about 28in. apart, and it was only given one cultivation, *i.e.*, as soon as the rows were to be seen.

Mr. E. T. Wray (Lameroo) had grown a fair amount of kale, but it was attacked by aphis.

Mr. Colebatch remarked that the aphis was not so destructive on kale as was the case with rape. The best treatment was to feed the crop off with a few sheep and allow it to reshoot.

Mr. R. L. Beddome (Parrakie) inquired if there were danger of the plants being destroyed by frost if lucerne were drilled by itself in the early autumn.

Mr. Colebatch thought there was a big risk. If the seed were got in early, however, and the sheep were run over the crop for a couple of days before the cold weather set in it would be hardier. Where they were endeavoring to establish a permanent plot of lucerne it was not advisable to sow with a nurse crop. They could not expect to get a good sward of lucerne and at the same time grow a crop of grain.

Mr. R. Jacobs (Geranium) last year sowed peas on red sandy land, and they were considerably blown about by the wind. Thin sowing, he thought, was not as good as thick sowing.

Mr. H. G. Johnston (Parilla) had come to the conclusion, after experimenting, that it was advisable to sow through every hoe on the drill.

Mr. A. J. A. Koch (Lameroo) inquired whether, in the case of peas for feeding off, sown on sand rises, the sand would in any way detrimentally affect the sheep.

Mr. Colebatch did not think there would be trouble through the sand getting into the stomach of the sheep.

Mr. W. Tyler (Wilkawatt) mentioned that a farmer in the district was drilling lime into the land with the idea of checking the growth of sorrel.

Mr. Colebatch stated that in light sandy land, situated 10 miles east of Mount Gambier, experimental plots had been sown with peas, with the addition of lime, gypsum, &c. On those parts where the lime had been applied there had been practically no sorrel, but there was a heavy growth of this weed where other manures had been applied. The probability was that in a well-drained sandy land there was a likelihood of the lime keeping the sorrel in check, but whether it was economically practicable to add sufficient lime to the soil to keep the weed under was not yet determined. Less than half a ton to the acre would show little effect. However, on light land, where the summer working was likely to cause drift, the sorrel might be of considerable benefit to them.

Mr. F. Norton (Geranium) had found that Cape oats grew very quickly when late sown, say after the wheat was finished. He had also tried oats and peas together, the latter being sown through every drill, and little trouble was experienced with the wind. Lucerne would be very profitable in this district. He had tufts growing in different parts of his property, and these had stood a dry spell last year very well. Autumn sowing of lucerne and English grasses was preferable in this district, because they then became well established before the dry weather came on. At Riverton he had sown lucerne with the wheat on 50 acres. The crop was first reaped, and then the straw was cut for hay. He believed that the sooner they commenced keeping stock and growing forage crops the better. He asked whether it was of advantage to roll peas, and whether this crop would eradicate or prevent the spread of sorrel.

Mr. Colebatch thought that in light land such as they had here, particularly if they wished to harvest the crop, it would be a good idea to roll the peas. He was not prepared to say that peas would eradicate sorrel, but they certainly checked its growth considerably.

POULTRY IN PINNAROO.

The Poultry Expert, in the course of an address on the breeding, feeding, and housing of poultry, remarked that Pinnaroo was one of the best districts in the State for poultry, and it was pleasing to notice that already a first-class up-to-date plant had been erected at Lameroo. It had been amply proved that kale, rape, and lucerne could be well grown in the district, and these fodders were of considerable value for feeding. The time had now come for the farmer to look at the farm fowls from a different point of view from that of former years. The old method was to have a few hundred birds running round, and in spite of the fact that in those days the price of eggs was between 3d. and 4d. per dozen, the proceeds in many cases had been considerable. With the introduction of the fox, however, the turkey industry was almost wiped out, and in many parts it was now very difficult to keep fowls. The plan he recommended was to build a fox-proof yard, about one acre in extent, and inside this erect a good house. In too many places the fowls had to roost in stables, and these became badly infested with poultry tick and other vermin. Good straight saplings were necessary for the yard, and the wire netting should be tied down to a tightly stretched wire buried 6in. below the ground. The netting should be at least 6ft. 6in. above the surface of the ground. Old boxes, palings, and such like material, were not satisfactory for use in building the house. Galvanized iron was best. This was vermin-proof. There should be breeding yards, and yards for the laying hens kept separately. A one-acre yard with a house 40ft. long by 15ft. wide, with the perches set all on the one level, would be sufficient to accommodate 500 hens. The male birds should be kept out of the laying stock. They were unnecessary and only spoilt the eggs. The breeding pens should be built in a continuous row to the following dimensions :—Each house 9ft. long by 5ft. high in front and 4ft. at rear, roof of 5ft. iron ; thus giving a floor space of 9ft. by 4ft. 6in. In front of each house a yard 9ft. wide and 40ft. long should be provided. Each house would provide accommodation for one male bird and 10 hens. In this district, considering the facilities for marketing, they should be able to make from 6s. to 7s. per annum per head from their hens, and the cockerels would practically pay their cost of rearing. From 100 to 500 birds could be kept on practically every farm in the district, but he did not believe in allowing them to run at large over the holdings. That farmers were taking an interest in the business was clear from the fact that in the farmers' class at the Parafield Egg-laying Competitions they had 29 entries. Five years ago it would have been practically impossible to select that number of farmers keeping first-class stock in South Australia. There was a desire amongst farmers in nearly every district to secure better stock.

Food and Feeding.

Wheat was the staple food for fowls, and when they could give them a change to oats it would be found to improve the health and egg-producing capacities, and probably at the same time cheapen the cost of feeding. Oats were rich in protein, and contained more fat than wheat. It was not necessary to go in for the soft feeding of mash, &c. If they adopted the scratching system the feeding would involve little time and trouble. A good layer of straw should be put in the house, and all the grain should be thrown into this scratching litter, and in this the hens would have to work for it. The exercise was an aid to digestion. Kale and lucerne (especially the Arabian variety) made excellent feed. The latter could be given when green, or, when dry, chaffed and steamed.

Marketing Eggs.

There was need for considerable improvement in South Australia with regard to the marketing of eggs. If the merchant could not guarantee that the eggs would turn out in good condition in Victoria or New South Wales, he could not afford to pay the top market prices for them. Infertile eggs only should be sent in. All surplus male birds should be done away with, as the hens would lay from 10 per cent. to 15 per cent. more when these were absent. Further, he felt sure the marketing of infertile eggs only would result in an all-round improvement of 1d. or 1½d. per dozen in the market price. They should not overlook the fact that if a broody hen sat on a fertile egg for only six hours germination took place, and at the end of 10 days this egg became rotten. Dirty eggs were not wanted by the consumer, therefore plenty of straw should be provided in the houses. There was now a good demand for eggs, and last year the average price in Adelaide was 1s. 1d. per dozen wholesale.

Questions.

Mr. E. J. Trowbridge (Lameroo) desired to know whether in-breeding between male and female birds from the same parents was advisable when they were 12 months old.

Mr. Laurie replied that it was good breeding to cross the sire on the daughters when they were two years old, but it was not wise to breed as suggested by the questioner. In-breeding for the purpose of fixing types and characteristics was all right, but it was not advisable to get too close. While it accentuated good points it also accentuated bad ones. In any case they should not breed from hens until they were two seasons old. The result of this would probably be a lack of size and constitution in the progeny. With cockerels, however, the case was different, for a cockerel at 12 months old was a vigorous bird.

Mr. A. J. A. Koch (Lameroo) said the time it took to feed a flock of laying hens night and morning on oats and wheat as recommended by Mr. Laurie only amounted to about 10 minutes daily. Last year from two Leghorn hens and one cockerel he bred 25 birds, which were now laying satisfactorily. From five White Orpington hens and one cockerel he had 34 birds, which were fine table poultry, but were not quite satisfactory in so far as laying was concerned. He was satisfied that if the farmer kept a flock of hens and looked after and fed them well he would derive a good income from them.

Mr. P. J. Edwards (Pinnaroo) had found that the hens would not eat oats readily if they were in the habit of eating wheat.

Mr. Laurie said fowls did not like some varieties of oats, which were very tough and husky.

Mr. Beddome (Parrakie) asked whether fowls would do well if kept enclosed and fed on a grain diet.

Mr. Laurie replied that while they might do all right, they would very likely become stale. There was an insufficiency of mineral and salt in the wheat; oats were better if they were plump; maize was too rich; and in peas fat was practically absent; barley was unsatisfactory—it was too starchy. The hens, however, would do all right on rye. Green feed was essential.

Mr. J. Gray (Claypan Bore) desired to know whether it was necessary to provide meatmeal or charcoal grit wher the fowls were enclosed.

Mr. Laurie said charcoal was a good antiseptic, and it was a good practice to use this. Rabbits were as good as meatmeal when they were available.

Mr. Bowmans (Wilkawatt) asked whether it was advisable to give the soft feed in the morning or evening.

Mr. Laurie mentioned that at the egg-laying competitions the practice was to give a light feed of mash with meatmeal in the morning. However, it could be fed morning or evening. Bran used in mashes should always be scalded.

Mr. J. Gray (Claypan Bore) had enclosed a large area for a yard, and had built a house for the pullets, of which he had about 200. There was a large amount of scrub in the yard. The laying had not been satisfactory, despite the feeding of bran mash in the morning and grain at night and green feed during the day. About one month ago they commenced to lay well, but at present they were only giving about half a dozen eggs daily. Some of the birds had taken to roosting in the mallee.

Mr. Laurie pointed out that hens which were roosting in the scrub would not lay well.

TAKEALL.

This subject was brought forward by Mr. W. J. Trowbridge, of the Lameroo Branch, who pointed out that the disease was due to a fungus which attached itself to the roots of the wheat plant. What chiefly concerned the farmer was the means he was to adopt in eradicating it. From observations, he had found that working the land dry, especially fallow land, was one of the greatest mistakes they could make. It was almost sure to result in the crop being badly affected. Continuous cropping of sandy land also seemed to encourage the trouble. He thought it wise not to put any land under crop for three or more years in succession before allowing it to lie out for a season. After the shoots were destroyed a good covering of natural grass was secured. When fallowing the land for subsequent cropping he got on to it early in June or July, ploughing to the depth most suitable to the nature of the soil being dealt with, which, in the case of his farm, was about 3in. Care should be taken to keep the ground free of weeds during the summer, as these provided a host for the takeall. The growth of crops, such as oats, which were immune to the fungus was advisable. The best preventive measures were early fallowing and keeping the land clean during the summer months, and not cropping for more than three successive years as a maximum.

Mr. Mill (Clanfield) mentioned that silver grass provided a host for the fungus. Oats sown after wheat which had been badly affected had been found to do remarkably well. Crops on strong clay land had been attacked by takeall in the South-East.

Mr. H. Ledger (Pinnaroo) produced three samples of wheat taken from a field of 200 acres. One plant presented a very poor appearance; this had been growing on the strongest soil in the paddock. His experience was that takeall was encouraged by sowing the seed in dry ground. When the wheat germinated immediately, the plant came away healthy, but if germination were delayed through a lack of moisture, the wheat was attacked by the fungus.

Professor Perkins pointed out that the name "takeall" had given rise to a good deal of misconception. There was no doubt that if they put in a crop under poor circumstances they might get malting if the grain was half moist, and patches would present the appearance of being affected by takeall. At the same time there was a distinct disease, which could only be determined by the presence of a specific fungus. When the plant was attacked by the disease, beneath the sheath of the bottom leaf black spots would be found. Possibly certain conditions of the soil favored the development of this. If the ground were relatively loose the disease seemed to be favored. It was most prevalent in the lighter lands. Mildew might be mistaken for it, and eel worms frequently caused conditions that looked like takeall. Oats were generally regarded as immune, but the Board of Agriculture in England had found that they were liable to be attacked in that land. Among the conditions which seemed to favor the disease was the defective preparation of the seed bed. If they kept the fallow clean they reduced the danger, because some host plants might grow on the fallow.

Mr. M. Shannon (Parilla) agreed that takeall was more prevalent in sandy land. Early fallowing when the land was in a wet condition was a good preventive measure. It was also essential to have the land thoroughly clean before ploughing. In some cases the ploughing in of the stubble encouraged the disease.

Mr. F. W. Eime (Lameroo) said takeall was one of the results of hurrying the land under crop three or four years in succession, without giving it proper cultivation. If farmers would go in more for growing and feeding off oats they would have less trouble with the disease. His average yield for the nine years he had been in the district had been 15bush.

Mr. F. Norton (Geranium) had found that if he put in two crops of wheat and then one of oats he had little trouble with the takeall.

Mr. F. Coleman (Advisory Board) indorsed the remarks of Professor Perkins. The samples of wheat exhibited by Mr. Ledger were not affected with takeall. He suggested that the application of lime or wood ashes to patches which were producing poor crops, as in this case, might result in improvement.

Mr. J. Jacobs (Geranium) had tried nitrate of soda on these patches, with very good results.

Evening Session.

FREE PARLIAMENT.

A number of questions were handed to the various experts for reply.

Mr. Colebatch said it was unfortunately necessary to burn stubble under certain conditions, but only in so far as it was necessary to reclaim the land was the practice permissible.

A delegate inquired the reason wheat growing on sandhills in some cases turned yellow. Professor Perkins replied that the yellow color of the wheat was an indication that the land was deficient in nitrates, but there were many causes which would result in the crop being unhealthy in this way. He doubted whether rape sown in spring in this district would do well.

TURNIPS.

Professor Perkins pointed out that in countries where turnips were grown, they were essentially spring crops, and although they could grow good turnips in most parts of the State in the winter, he could not see that as a winter crop they were much good. The trouble with the winter-sown turnips was that they were ready for use generally when there was plenty of feed available, and they ran up to seed as soon as the hot weather set in. If, however, they could grow them in summer, there were very few crops that were more profitable. Rape was better sown in autumn. When they put in this crop at Roseworthy they used about 4lbs. of seed to the acre.

AN EXPERIMENTAL FARM.

The Hon. Minister of Agriculture was asked whether he was in favor of establishing an experimental station for the benefit of the farmers east of the River Murray, to which he replied that there was already a Government farm at Veitch's Well, and while this might not effect to any great extent farmers on this particular line of railway, it was on similar country and under similar conditions (perhaps with a little lighter rainfall) to those existing at Pinnaroo. He did not think it wise to have too many experimental stations. More good could be done, so far as experimental work was concerned, by the conduct by farmers, under the guidance of the departmental officers, of such tests as were being carried out by Messrs. Coleman, of Saddleworth ; Pengilly, of Aldinga ; Griffin, of Hammond; and Pope Bros., of Mount Barker.

RESULTS AT ROSEWORTHY COLLEGE.

Professor A. J. Perkins (Principal of the Agricultural College, Roseworthy) delivered an address, in which he gave much information, gathered as a result of experiments conducted at that institution. The statement had been attributed to him that " the Pinnaroo country would not keep a rabbit." On carefully reading the evidence he gave before the commission which inquired into the advisableness of constructing the railway to open up the district, he found that the only allusion to rabbits was contained in an expression of the hope that if the Forest Department should be given control of the sandhills, so that it might plant them with a view to prevent sand-drift, it should be obliged to surround them with vermin-proof fencing. He had always thought that the country would produce good wheat on the better class of land, and that was the principal bone of contention in those days. He was still as strongly convinced as ever, though, that they would inevitably suffer, not only as individuals, but as a district, if they failed to take certain precautions to prevent the shifting of the sand.

MORE MANURE.

The time was coming when they would recognise the wisdom of applying heavier dressings of phosphatic manures than they were inclined, perhaps, to use now. Comparatively light dressings were all right where the land contained an abundance of phosphoric acid, and they had in mind only the production of grain ; but sooner or later they would go in for grazing live stock, and he believed that there was no more profitable form of live stock in that connection than sheep. To enable them to carry the largest number of sheep at the greatest profit it was essential that the land should be treated in the most satisfactory manner. To ascertain the influence of various dressings of phosphatic manures on the carrying capacity of land he had initiated on the College Farm experiments which had now been in progress for about three years. A block of practically virgin country (so far as the application of artificial fertilisers was concerned) was divided into three-acre paddocks, and in each was laid out three plots - one to be treated as bare fallow, another to carry wheat, and the third to be grassed. There were several of these three-acre blocks. In one case he arranged that throughout no manure should be applied to the land. The next series was to receive ½cwt. of manure, the third 1cwt., the fourth 2cwts., and the fifth 3cwts. Although the investigations had been proceeding for only a short period, already the results had revealed a marked difference, as would be seen by the following table :—

ROTATION—BARE FALLOW, WHEAT, PASTURE (1910-13.)

Super. per Acre.	Produce per Acre.			Grain per Acre.		Sheep per Acre. Pasture 12 Months.	Sheep per Acre. Stubble, Dec. to March.	Gross Return per Acre for Two Years.			Profit per Acre Over no Manure.		
Cwts.	T.	cwts.	lbs.	Bush.	lbs.			£	s.	d.	£	s.	d.
None....	1	2	96	10	26	0·48	1·22	2	9	10		—	
½	1	9	71	17	42	0·63	1·62	3	19	6	1	7	7
1	1	15	64	19	20	0·80	2·03	4	9	3	1	15	3
2	1	16	81	19	44	0·99	2·45	4	16	3	1	18	1
3	1	16	34	19	11	1·03	2·56	4	15	4	1	13	0

In arriving at the financial returns the wheat was valued at 3s. 6d. a bushel, the super. at £4 2s. 6d. per ton, and the sheep were taken at 15s. a head per annum. He emphasized the fact that the full benefit of heavy dressings of superphosphates were not realised until approximately a ton to the acre had been applied. In good years he had had fields carrying four sheep to the acre. He took it that the Pinnaroo land was not good grazing land at first, but he felt convinced that if when sowing their wheat they put on more super. they would gradually cause it to become really good grazing country. In most cases the land was light, and therefore the question of humus was of vital importance. So far they had been utilising the supply which Nature had accumulated in the soil during thousands of years, but by cultivation, and especially bare fallowing, they would ultimately exhaust it, and if they did not keep stock they soon would work the land out. The more care they took to store up humus the better it would be for them and for the crops.

CROPS ON SAND.

Reference had been made by speakers to the effect that the only time to get good crops from sand was after a burn. He had ascertained by experiment that on sand ridges (but not on heavy land) it paid well to apply ½cwt. each of sulphate of potash and nitrate of soda to the acre. He was satisfied that if they adopted that plan their crops would not go yellow. Relatively to the influence of nitrate of soda the appended results were interesting :--

	2cwts. Super, 1cwt. Nitrate, at Seeding.		2cwts. Super. 1cwt. Nitrate, in Spring.		2cwts. Super.		No Manure.	
	Bush.	lbs.	Bush.	lbs.	Bush.	lbs.	Bush.	lbs.

FORAGE CROPS.

He was glad to learn that peas did well in the Pinnaroo district, because they were exceedingly useful, both for forage and as a means of improving the fertility of the soil. The trouble with most forage crops was to work them in regularly with the main crops. Wheat was the principal crop of value to the farmers, and anything which interfered with it unduly had to be left. While fully alive to the worth of peas, he had to acknowledge that there was no crop which tended more to dirty the land. They must be fed down either when comparatively green, or permitted to go to seed. It was not necessary to sow peas before wheat. Their fertilising properties were not lost when the rotation was bare fallow, wheat, peas, and then bare fallow again. Peas furnished feed generally when there was no other, and he entirely agreed with those who considered that one could not grow a better crop. Kale was supposed to do well in very heavy ground, and consequently rape should be better suited to that country. If they could be grown in the summer, turnips would be excellent. If they were in difficulties and wanted feed quickly they would be well advised to try white mustard. Nothing grew faster in the winter months, or could be more suitable for stock. Lucerne sown in a crop had much to commend it, and gratifying success had been achieved in that respect at Roseworthy. It was a great advantage to have it growing in their stubbles. He always sowed a certain quantity of seed in the hay crops. Sorghum was an invaluable crop in many ways, but it almost invariably reduced the ensuing grain yield. The following table indicated results recorded at the College :—

	Wheat After Bare Fallow.					Wheat After Sorghum.				
	Total Produce per Acre.			Grain per Acre.		Total Produce per Acre.			Grain per Acre.	
	T.	c.	lbs.	Bush.	lbs.	T.	c.	lbs.	Bush.	lbs.
1906	2	8	100	23	48	2	0	39	18	3
1907	1	8	92	20	31	0	17	22	13	7
1908	2	11	26	32	47	2	9	96	28	17
1909	2	7	61	29	54	2	1	49	20	44
1910	2	5	98	19	49	2	0	44	18	25
1911	1	8	9	14	7	1	3	8	12	38
1912	1	6	32	18	11	1	10	33	20	18
Means	1	19	60	22	44	1	14	74	18	47

The growing of sorghum resolved itself into a matter of sowing it late enough, or of cutting it down as he did at Roseworthy, making ensilage, and trusting to the summer rains to produce a second growth.

CONTINUOUS WHEAT-CROPPING.

Conclusive evidence of the undesirableness of keeping the land continuously under wheat was provided by the results of experiments conducted over a period of five years.

Grain per Acre.

	No Manure.		2cwts. Super.		2cwts. Super. 1cwt. Nitrate of Soda. 1cwt. Sulphate of Potash.	
	Bush.	lbs.	Bush.	lbs.	Bush.	lbs.
1905	15	25	32	12	31	26
1906	4	35	6	49	6	30
1907	4	38	2	11	3	59
1908	Bare fallow		Bare fallow		Bare fallow	
1909	31	55	31	27	35	41

So poor was the third crop in each instance that it was determined to try the effects of one year of bare fallow. They would see what a tremendous difference it had made. Why the grain from the unmanured plot should have exceeded that from the plot dressed with the super. was more than he could say.

QUESTIONS.

In answer to inquiries Professor Perkins said the best plan, when applying nitrate of soda, was to distribute it as a top dressing with a broadcaster. Although weight for weight sulphate of ammonia and nitrate of soda cost the same, the former was the cheaper. At the same time, as there were different grades, it was not so dependable. Nitrate of soda suited light land, and sulphate of ammonia heavy land. On land rich in lime he would use nitrate of soda, and in most countries where the rainfall was heavy, it was applied in spring. In a general way, however, he advised broadcasting it immediately after seeding. Nitrate of lime ought to be better than nitrate of soda as a top dressing, particularly for a district lacking in lime. If it were obtainable at the same price he certainly would prefer it. At the College mustard seed was sown as early as possible in the autumn, at the rate of 3lbs. or 4lbs. to the acre. Even when sown in July it ran away quickly. He used it mostly when he feared a shortage of early feed.

TREE-PLANTING AND EXPERIMENTS.

Mr. F. Coleman (Advisory Board) expressed a desire to impress on the farmers in this district the necessity for tree-planting. There were corners of the holdings which could well be fenced off and devoted to this purpose. The conduct of experimental plots, he pointed out, entailed the separate harvesting of small areas of crop, and whilst this would involve a fair amount of time it would give them the opportunity of securing wheat very suitable for seed purposes. He was of the opinion that a good deal of the land in this district was not strong enough for mustard.

NEXT CONFERENCE.

It was decided that the next Conference should be held at Lameroo.

THANKS.

The gathering closed with votes of thanks to the Minister of Agriculture, officers of the Department, members of the Advisory Board, and the gentlemen responsible for local arrangements.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

October 8th and November 12th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

Amyton, August 12.

(Average annual rainfall, 11·82in.)

Present.—Messrs. T. O'Donoghue (chair), T. Ward, A. J. Phillis, M. Corcoran, W. Gum, H. Gum, and S. Thomas (Hon. Sec.).

Sheep on the Farm.—Mr. T. O'Donoghue read a paper on this subject. Sheep were of considerable value, he said, in keeping down weeds. He preferred the Merino, as they were easily kept within the fences. They yielded better wool, and on the average returned more money per sheep than crossbreds. The difficulty in lamb-raising in this district was to get them fat for freezing. The returns for wool per sheep for the last three years had been—1910, 5s. 10d.; 1911, 5s. 1d.; 1912, 5s. 11d. In three years he had received £187, and had saved about 10s. a week for butcher's meat. The feed consumed by the sheep would have been of no use to other stock, as they only had the run of the paddock after other stock had finished with it.

Carrieton, August 14.

(Average annual rainfall, 12·22in.)

Present.—Messrs. W. E. Radford (chair), F. Kraeger, G. Fuller, G. M. Williams, F. Vater, and J. W. Bock (Hon. Sec.).

Threshing Wheat.—In a paper on this subject, Mr. Kraeger pointed out that owing to the uncertainty of the seasons in the north, and the advisability of storing all fodder that was available, the practice of binding and threshing wheat was to be recommended. He adopted this course last year, cut his crop before it was quite ripe, and after threshing it, mixed the chaff and straw, which made excellent fodder for horses and milch cows. The machine could be worked by a 5-h.p. engine, and would deal with about six to eight bags per hour. Harvesting arrangements might be facilitated by growing varieties of wheat that ripened at different times. Even if the farmers continued to cut portion of their crops for hay, they would gain by binding and threshing 100 acres or so when it was nearly ripe, thus ensuring good feed. There was no loss of grain, the sample was good, and the threshing could be done when the general harvesting was disposed of.

Coomooroo, August 16.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. E. Berriman (chair), J. Brown, R. Brice, G. B. Lillicrapp, E. Brice, L. Avery, W. M. Robertson (Hon. Sec.), and two visitors.

Tree and Shrub-Planting.—Mr. E. D. Kirkland contributed a paper, in which he recommended farmers to make a practice of planting a few trees every year. The area to be planted should be well fenced and the ground fallowed during the year prior to putting in the trees. If there were a firm subsoil or a limestone crust, square holes should be sunk. Small trees and shrubs around the homestead could be protected from small stock by having a piece of rabbit netting supported by three or four stakes placed around them. He had found that trees planted in the autumn did well, but it was necessary to protect them from the frosts during the winter. Sugar gums, sheoaks, tamarisks, pepper trees, blue berry, and boxthorn had done very well on his property. In discussing the subject, Mr. L. Avery mentioned that care should be taken in the selection of the land on which different varieties of trees were planted. Heavy clay soils suited gum trees, whilst pepper trees flourished in lighter soils. He preferred the olive as a hedge plant. Mr. G. B. Lillicrapp pointed out that it was necessary to plant trees where there was a good depth of soil, and Mr. R. Brice advised the utilisation of the corners of paddocks and waste land for this purpose. Mr. Berriman thought the best means of preparing land for trees was to plough it to a good depth a few months before planting. No good was done by planting a tree in a hole in which a tree had previously died.

Davenport, July 17.

(Average annual rainfall, 9in. to 10in.)

Present.—Messrs. Holdsworth (chair), Bice, Bothwell, Roberts, Gosden, Messenger and Lecky (Hon. Sec.).

Railways and Water Conservation.—Mr. Roberts read a short paper on this subject. He expressed the view that it was unwise to construct railways in districts where there was not an assured supply of water, and drew attention to the existence of many natural springs in this district which could be utilised for irrigation purposes if dams were constructed in suitable places.

Hookina, August 12.

(Average annual rainfall, 12in.)

Present.—Messrs. D. Madigan (chair), P. Henschke, H. Huddlestone, J. J. Henschke, P. Murphy, sen., B. Murphy, J. Carn, P. and T. Kelly, C. F. Stone, and two visitors.

Wool-classing.—Mr. J. Henschke delivered an address, in which he advised members to keep their wether, hogget, and ewe wool separate, and also to put the broken fleeces by themselves. Loose dirt and dust should be shaken out of the fleeces, and they should be skirted of dirty wool and locks.

Harvesting.—Mr. P. Kelly preferred the use of the harvester for gathering the crop. Straw should be used in the place of cocky chaff for fodder. The Chairman would cut the crop, thrash it, and stack the straw for fodder.

Disc Cultivator.—Mr. L. Woods read a paper as follows:—"The disc cultivator is the best implement for working the land in this dry district, for it thoroughly pulverises the soil, turns it completely over, and leaves an almost perfect seed bed. It does splendid work in stubble land where the straw would have to be raked before any other implement could be worked, and thus saves a good deal of time. When fallowing, six medium horses will work it easily to a depth of 3in. to 4in. in land that has been worked before." Members agreed that the disc cultivator was a useful implement, but it should not be used for fallowing.

Morchard, July 19.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. A. J. Scriven (chair), W. Toop, W. Keauschner, E. J. Kitto, H. A. Toop, E. D. Kirkland, W. Reichstein, G. Parsons, W. Munro, R. Kitto, H. Laskey, R. Jasper, and B. S. McCallum (Hon. Sec.).

Making Farm Life Attractive.—The Chairman read a paper comparing the conveniences of city life with those of the country, and suggesting means whereby the latter could be made much more attractive. He considered that in many instances a want of thought rather than a consideration of the cost was responsible for the lack of conveniences in farmers' homes. In the city, for instance, it was a great convenience to have the water laid on. On almost every farm water could be laid on to the house, either from the tank by the windmill, or by means of a raised tank connected with a tap in the kitchen. The tank could be filled from the roof of the house and a pipe fixed to take the overflow into the underground tank. Suburban gardens were attractive, but on almost every farm flowers and fruit could be grown. Apricots and peaches did fairly well anywhere in the North. The engine power, with which most farms were equipped, might well be used with a circular saw to cut the wood into reasonable lengths, so that the country housewives might in this respect be as well catered for as those in the city. Frequently an hour or two could be well spared after hay had been chaffed and the engine was in working order to cut a supply of firewood. It was a fine idea to provide a tennis court, or similar attraction, on which the younger members of adjoining holdings could spend time occasionally. Two or three trap and saddle horses, and a buggy, sulky, or masher cart should be kept, to enable the womenfolk to visit the store or the neighbors. Out-of-date implements, ill-fed horses, and harness in disrepair, all contributed to make the farm life unattractive. Stables and chaff sheds should be close together, and there should be a space in front of the mangers to permit of feeding.

Morchard, August 16.

(Average annual rainfall, 11in. to 12in.)

PRESENT.—Messrs. J. Scriven (chair), W. Reichstein, W. Kueschner, H. Kupke, G. Parsons, W. A. Toop, E. D. Kirkland, W. Toop, W. Munro, H. A. Toop, B. S. McCallum (Hon. Sec.), and four visitors.

HOMESTEAD MEETING.—Members inspected the stock, crops, and outbuildings on Mr. W. Toop's farm. The engine and chaffing plant came in for considerable notice on the part of the visitors.

BULK HANDLING OF WHEAT.—A paper on this subject was read, and members agreed that some more economical system of handling wheat should be introduced.

WORKSHOP ON THE FARM.—Mr. W. C. Kuerschner read a paper on this subject. The workshop, he said, was an important requirement on the up-to-date farm. It should be sufficiently large to enable a person to work with comfort, and to hold all the machinery and tools required. The blacksmith's outfit should consist of a blower, an anvil weighing from 80lbs. to 112lbs., tongs, drilling machine, vice, taps and dies, hammers, cold chisels, files. Shoeingsmith's tools might also be added. Continuing, the paper read—" Another corner of the workshop should be occupied by a carpenter's bench, with a tool rack, on which the following would be found useful :—Saws, brace and bits, draw knife, plane, chisels, and a half-round wood rasp, together with a good assortment of nails and screws. A small saddler's repairing outfit will also be found very handy, as breakages in harness are constantly occurring where several teams are at work. A leather punch and a packet of assorted copper rivets will do most of the rough work, but if a man is handy with a needle he might go in for sewing, as it makes a neater job. A few other tools, &c., which should always be found in a workshop are a boot last and a shoemaker's hammer, with a supply of brass sprigs for half-soleing boots and shoes, a soldering iron, snips, stick of solder and spirits of salts, spirit level, and trowel. With a workshop and outfit, such as I have described, a man need never be idle on a wet day, besides saving many pounds in his blacksmith's and carpenter's bill." Messrs. W. Reichstein and H. Kupke agreed with the writer. Mr. H. A. Toop thought collar needles and check for relining collars might well be included. Mr. Scriven would add a hack saw.

Mount Remarkable, August 13.

(Average annual rainfall, 14·43in.)

PRESENT.—Messrs. N. S. Giles, B.Sc. (chair), W. J. Oldland, L. A. Bauer, W. Foot, R. G. Fiebig, J. McIntosh, F. B. Smith, G. Yates, jun., D. H. Clarke, and H. H. Davie (Hon. Sec.).

TIMBER DESTRUCTION.—The Branch decided to take steps to endeavor to preserve the natural timber on Mount Remarkable, and to approach the Government with this idea in view.

LUCERNE.—Mr. Foot recommended mixing 5lbs. to 7lbs. of lucerne seed with ½cwt. of wood ashes, drilling this lightly on an acre of ground.

SILO.—The Secretary said a good, cheap silo, for a small establishment could be made of stout posts in pairs, or stouter posts with two battens each side, having the ends of horizontal slabs pushed down between the pairs, with pieces of tin or plain galvanized iron nailed inside over all the interstices to exclude the air. On top of the final weights straw could be placed as on a shed, thus providing a roof.

Orroroo, July 12.

(Average annual rainfall, 13·42in.)

PRESENT.—Messrs. J. B. McDougall (chair), C. R. Macdonald, E. Turley, S. Hook, J. C. Hagger, E. Langton, J. McNaughton, W. Collins, J. M. Cadzow, J. R. Chapman, T. H. Tapscott, L. R. Cottrell, W. B. Weger, H. Chapman, J. Lang, J. T. Northcott, L. Haynes, A. L. Brice (Hon. Sec.), and two visitors.

THE DRAUGHT HORSE.—A paper was contributed by Mr. J. M. Cadzow. In the early days, he said, draught horses were so scarce that a large number of settlers had to use bullocks for tilling the soil. As the early settlers began to make headway a demand sprang up for draught horses to take the place of bullocks, and the nearest place where they could be procured was Van Diemen's Land. These were a nice stamp of horse, but much smaller than those of the present day. They were extremely active, docile, and intelligent, and possessed fine robust constitutions. As might be expected, they were very expensive. As time went on large numbers of light horses came from New South Wales, the settlers crossed these with the Van Diemen's Land sires, and procured a useful horse. This cross was again mated to a draught sire, a steady improvement taking place. About this time three notable sires were imported—Clyde and Argyle (Clydesdales), and Aggravation (Shire). Clyde was a fine acquisition to the colony, and no horse made a more marked improvement to the draught stock of South Australia. Argyle had a long and useful career; and Aggravation also left a fine class of horse. The colony was by this time (about 50 years ago) progressing rapidly, and the demand for draught horses was keener than ever. When settlers began to spread north, east, and west of Clare, stallions were imported from Victoria, New Zealand, and Scotland. In the last 40 or 50 years breeders had had a fine choice of sires. At the present time the draught stock is superior to the draught stock of most of the agricultural countries of the world. In the early days settlers sometimes took two days to travel a single mare to meet a good stallion; many of these pioneers were illiterate, yet they were keen and competent judges of draught horses. They had a knowledge of the points and defects that the rising generation did not seem to possess. In breeding he advised avoiding the lanky animal, prefering the low-set type with well-balanced width of chest. If end appearances were all right there would be little wrong with the broadside view. The low-set type of horse was invariably the most active. The Shetland pony constituted a perfect model of a draught horse. All users of horses should give them a reasonable amount of care; they were well repaid by so doing.

Orroroo, August 9.

(Average annual rainfall, 13·42in.)

PRESENT.—Messrs. T. H. P. Tapscott, W. W. Collins, J. C. Hagger, S. S. and E. J. Hook, L. B. Cottrell, J. T. Northcott, E. Turley, J. M. Cadzow, J. B. McDougall, K. McLean, J. H. Nutt, C. R. McDonald, L. Haynes, J. McNaughton, J. Lang, J. Dennis, J. H. Brown, A. L. Brice (Hon. Sec.), and 12 visitors.

EXPLOSIVES AND TREE-PLANTING.—Members met at the homestead of Mr. J. B. McDougall to witness a demonstration of the use of explosives in connection with the planting of trees. Holes, 14ft. apart, were dug to a depth of 15in. A hole about 18in. deep was made in the centre of the larger holes, and into this a cartridge was placed, the hole being filled up with earth until about 2in. of the fuse projected. The explosions loosened the earth to a considerable depth. Trees were then planted, and to check the benefit of the practice a few trees were put in holes dug in the ordinary way. The results will be watched with interest by members.

Tarcowie, August 11.

(Average annual rainfall, about 15½in.)

PRESENT.—Messrs. A. Dempster (chair), A. C. Kotz, J. Breuer, J. B. Smith, W. Travers, J. O'Grady, J. Symons, D. Butterick, S. Harding, A. Kotz, J. R G. Thomas, M. McCarthy, C. McCann, W. J. Ninnis, J. Dempster, W. Ninnis, A. Shorowder, D. Murphy, P. Reynolds, T. Ninnis. J. Burgess, M. Murphy (Hon. Sec.).

FALLOW.—Mr. W. S. Bennett read a paper from which the following is taken:—"The claim made by many that deep fallowing will produce heavier crops than shallow fallowing is true only in so far as the succeeding cultivation is thorough. If fallowing is carried out to a depth of 6in. or 7in. it will not produce a heavier crop, unless the cultivation is carried out to almost the same depth. The best time for fallowing is when the soil is moist: not too wet, and above all not dry enough to turn the furrow in clods. Under these conditions, when ploughed 6in. or 7in. deep, and broken down with the harrow and then cultivated to a depth of about 3in. it is likely to make a double layer, fine on top and leaving at the bottom of the furrow spaces which in the dry weather of the summer allow the moisture retained by the fine top surface to evaporate. Although the top surface will be fine as far down as the culvitator has worked, the layer under that to the full depth of the ploughing will probably be made up of small spaces and more or less hardened clods. Ploughing to the depth mentioned must be a better preparation of the soil (where the soil will admit of it) than shallow ploughing, provided it is cultivated to the same depth. No plough will pack the soil so well together, especially at the bottom of the furrow, that the use of the cultivator to get it into a fit state to absorb and retain the maximum of moisture which falls upon it can be dispensed with. The object of deep fallowing is to make more plant food available for the ensuing crop and to retain more moisture. Unless the cultivating is as deep as the ploughing the soil is not pulverised to the full depth, and in the lower layer the plant food is really not made available to the plant. Instead of supplies of moisture being accumulated for the crop to draw on during dry spells an unpulverised and unpacked lower bed allows the supplies to evaporate, and thus forces the crop to rely upon rains coming just when needed. When these fail the crop must necessarily suffer. On the other hand, the system of deep ploughing when thoroughly pulverised must make more plant food readily available, and at the same time retain the maximum moisture with which a crop may safely come over a dry spell without sustaining any injury. If 6in. or 7in. of the soil is prepared so that it retains the maximum of moisture and makes the plant food therein more readily available, it will grow a richer and heavier crop than land which has not the same depth and storage capacity. On the other hand, however, I consider that land which has been ploughed 3in. deep and thoroughly pulpervised will produce quite as good, if not a better crop than land ploughed deeper and not thoroughly pulverised. The whole value of fallowing lies in the thorough pulverisation of the turned furrow; the finer and deeper the land is worked the greater the benefit to the ensuing crop. Of course, where the land that is to be fallowed is clean, if it is only ploughed and broken down with harrows this is a valuable preparation for the crop; but taking the seasons on an average, whether on deep or shallow ploughing, it will pay to thoroughly work the land down. It is not necessary to pack the land in this district. Of course, in fallowing one has to carefully observe the conditions of the land and be guided by circumstances. If the field to be ploughed is very dirty it will not do to plough deep: 2½in. is quite enough. It should be well turned over and broken down with heavy harrows, care being taken not to harrow when the land is wet. This will thoroughly loosen the land and ensure the winter rains starting all the rubbish. A good cultivation following this will make a good seed bed, and result in the land being clean when the crop is sown. In average seasons ploughing should be started as early as possible in June, and should be finished by the beginning of August. The land can then be broken down with the harrows and the cultivator put over it while it is still moist; thus preparing it to retain the moisture of the winter and spring rains. While the harrows are invaluable, they only make a fine top surface, while the cultivator makes a deep bed and also brings any clods to the surface where they can be dealt with. Where possible cultivate land twice. The latter working should be done in the latter part of the spring, and no moisture will be lost through evaporation. The land will then be ready for seeding, and the making of a good seed bed will be an easy matter; beside which the land will be in a better state to retain moisture through any falls of rain which might occur during the summer months. Fallowing simply makes the land more retentive of moisture, cleans it, and makes the plant food more readily available. I would suggest to the farmer who fallows one year and crops the next, that instead of fallowing the usual area at least one small paddock be cultivated and sown to oats or barley, with 80lbs. to 100lbs. of guano super. to the acre; to be fed off by stock, and then at seeding time to be ploughed up and seeded. This will ensure the farmer a double return from that paddock, besides enriching the soil by means of the roots of the crop, droppings of the sheep, and the guano. The amount of feed secured will more than compensate for the seed and super. used. To the farmer who crops his land on the three-year system the same will apply. Instead of leaving all the land for grazing, growing only the grass, wild oats, or the little wheat left behind the harvesters, he could crop it as above-mentioned, fallow the following year, and thus increase the returns besides enriching the land, and so gain a heavier yield from the principal crop. Constant cropping is a drain on the land; fallowing should be made more far-reaching in its effects than making available plant food." In discussing the subject Mr. W. J. Ninnis said he preferred a perfect mould from top to bottom for the retention of plant food. He considered continued cultivation disastrous. The Pekina land did not require deep ploughing. Mr. Symon advocated deep ploughing without the mould boards once in five years. Mr. W. Ninnis found that good work could be done by using the scarifier instead of the cultivator for deep work: it was stronger and broke the bottom better. Land could be cleaned better by cultivating with the scarifier than with the plough. Mr. T. Ninnis preferred to allow the land to remain fallow for two years before cropping. Mr. Dempster thought the price of land too high to allow of this practice being economically adopted. He preferred fallowing with the scarifier.

Warcowie, July 19.

(Average annual rainfall, 12·16in.)

Present.—Messrs. T. Donnellan (chair), Marron, Growden, W. Crossman, Hilder, F. Crossman, E. Jarvis, Telfer, B. Crossman, Feineler (Hon. Sec.), and 25 visitors.

Dairying.—The Dairy Expert, Mr. P. H. Suter, delivered an address on this subject. He advised farmers to carefully select their dairy herd, to pay careful attention to feeding and breeding, and recommended the marketing of milk and cream at frequent intervals. Cleanliness was an important factor, and in this regard, limewater for cleaning cream cans was of considerable value. Members expressed their appreciation of the remarks of the lecturer.

Wepowie, August 12.

(Average annual rainfall, 13in. to 14in.)

Present.—Messrs. J. Rielly (chair), M. M. Irvine, J. E. and C. Pearce. C. Knauerhase G. Roocke, W. T. Heitzel, G. Walker, J. Orrock (Hon. Sec.), and one visitor.

Farm Homestead.—In a paper on the subject of the laying out of the farm homestead, Mr. C. Pearce said the dwelling house should consist of four or five rooms, about 12ft. by 12ft. or 12ft. by 14ft., and be set on rising ground near the centre of the farm. An underground tank, 12ft. by 12ft. by 12ft. should be sunk adjacent to the building, and if this were not sufficiently large for the water caught by the roof a 1,000gall. tank could be set about 3ft. above the ground and connected with the kitchen with a pipe. The stables should be set about 6 chains from the house, facing north, and be about 60ft. long by 20ft. deep, with the mangers set on the lower side. It should consist of iron with pine uprights, giving accommodation for two horses in each stall. There should be a space of about 1ft. between the bottom of the walls and the ground to provide ventilation. A shed capable of holding about 12 tons of hay should be at one end. A good well sunk close to the stables would be found very handy. The blacksmith's shop should be sufficiently large to accommodate a harvester. Mr. Knauerhase thought convenience of position the essential factor in laying out the farm buildings.

Willowie, August 12.

(Average annual rainfall, 11·90in.)

Present.—Messrs. T. Hawke (chair), D. McCallum, J. Stone, L. McCallum, S. C. Greig, A. W. Howard, E. S. Bristow, S. McCallum, A. Gray, F. Richter, A. Wilkins, E. J. Kentish, L. Hughes, W. P. Foulis (Hon. Sec.), and one visitor.

Summer Fallow.—In an address on this subject, Mr. D. McCallum said it was an advantage to do some of the fallowing before seeding. Deep ploughing was advisable. Light friable soil, such as was met with on the local plains, could be worked at any time, and he advised fallowing in summer, the land being well-worked subsequently to keep it free of weeds. Mr. E. J. Kentish thought summer fallowing a good practice, as it encouraged the early germination of oats and weed seeds. Apart from this, it was no improvement on early fallow. Mr. Gray thought that if the land were worked lightly in the summer there would be a fine tilth to turn under. It was not advisable to sow the seed when the land was too wet, but moist sowing was better than dry. Oats would lie in the ground for a number of years and then germinate. Mr. S. McCallum pointed out that the practice of summer fallowing enabled one to deal with a larger area without increasing the horse strength. Deep ploughing was best, whilst shallow ploughing was more satisfactory than the use of the skim plough or scarifier. Mr. S. C. Greig thought it better to work the soil wet. Mr. Hawke mentioned the case of a farmer in this district who cropped half and fallowed half his farm each year, and put the seed in when the soil was moist; whilst the yields were not very heavy, the average was good, and the land was much more easily worked. It was not advisable to summer fallow land that had been left out, as it would turn up lumpy. Mr. J. Stone favored shallow summer fallowing. The land took in the first rains and seeds of weeds germinated early.

Wilmington, August 13.

(Average annual rainfall, 18·26in.)

Present.—Messrs. D. S. George (chair), S. George, Scheibner, Hannagan, Dühring, E. J. Gloede, J., G., and W. Schuppan, McGhee, Hill, Forbes, Scholefield, Benier, Pickering, Zimmermann, Slee, B. Jericho (Hon. Sec.).

Cows, Poultry, and Vegetables.—Mr. Forbes read a paper, from which the following is extracted:—"I am of opinion that a dairy is a profitable investment, some of the advantages being a continual supply of milk, cream, and butter for farm use, which helps to support the household, thereby decreasing the expenditure on food stuffs. A supply of cream or butter available for sale to a factory or a store is without doubt the greatest benefit from a farm dairy, in that it provides the household with cash or provisions and other requirements for their upkeep. The dairy also affords a supply of separated milk, which can be used for the rearing of calves. The milk also serves as a good food for pigs. The dairy herd should be made up of the best possible milking strain procurable at a reasonable price. It is quite common to see a large-framed cow (which, if fat, would do for the butcher) being used as a milch cow, whereas a much smaller cow of better milking qualities, with a smaller food capacity, could be obtained, such as the Jersey. I suggest that each farmer endeavor to gradually work into his farm such types of cows as combine milking qualities with size, and weed out the large unprofitable animals. This, I admit, will take time, but in the end this herd will be giving the highest results. Poultry are a source of revenue to the farm. The amount they return for the little attention bestowed on them is remarkable. They are one of the best paying lines on the farm, and it is a great surprise that poultry-breeding is not more extensively carried on, to the farmer's own decided advantage. I admit that when loose they have a habit of scratching haystacks, &c., but all this inconvenience can be obviated if a large area is wire netted for their exclusive use. This will also enable the poultry to be better kept under observation. The scraggy and ill-conditioned birds should be weeded out. This will allow of a small poultry plant being gradually worked up, consisting of good laying strains, preferably White Leghorns or Black Minorcas. A small area should be set aside on every farm for a vegetable garden. It should be well fenced and supplied with stable manure, and ploughed in as required. It is also advisable, if the garden is to be the success it should, that a permanent supply of water be available. In the absence of reservoir water, wells, bores, or dams should be provided, and water conveyed to the garden as required. The water supply could also be used for stock, &c., thereby serving a double purpose, and so not be a straight out charge on the garden. The most used vegetables, of course, should be grown, such as potatoes, onions, cabbages, cauliflowers, turnips, lettuces, and so on; pumpkins, trombones, marrows, squashes, and piemelons should also receive attention, and if carefully picked when ripe, and placed in a dry airy shed, will keep for some time. The piemelon, in particular, I have known keep for months. It can be utilised for melon pies, jams, and, further, when plentiful, has been used as a fodder for pigs and cows by being chopped into chunks. There is also another vegetable I should like to draw attention to, and that is rape; the value of which is not truly appreciated. It can be sown to provide 'early greens' for the table, even before the earliest cabbages are fit to cut. Moreover, it can be cut three times, and should it grow beyond table use it is a good food for poultry, sheep, and cattle, for, if allowed to grow, will reach a height of 5ft. and more. There is quite a variety of greenfeed to choose from for the dairy herd, such as barley, lucerne, maize, sorghum, thousand-headed kale, mangel wurzel, rape, &c. The advantages of lucerne and barley are too well known to need mention, but I would like to point out the value of maize, which, if grown under good conditions, can be cut at least twice, and in some instances three times. This is a very succulent fodder. With mangel wurzels, both the tops and bottoms are used for food. When the tops are finished, the wurzels can be dug up and placed in a dry shed, and fed to pigs or cows by being sliced up as required. It is wise to experiment with some fodder grasses, such as *Paspalum dilitatum* and *Phalaris commutata*, which are both good plants. the value of which has yet to be determined.

Wirrabara, August 16.

(Average annual rainfall, 18·91in.)

Present.—Messrs. C. H. Curnow (chair), F. Cockington, E. Kavanagh, C. Hollett, C. F. H. Borgas, A. E. Stott, P. J. Curnow, L. S. Cobiac, R. Curtis, W. Bowman, W. Marner, H. and O. Woodlands, P. R. Hoskins, G. Hollett, E. J. Stevens, E. Pitman, A. G. Grant, H. G. Hastings, J. Fitzgerald.

Spraying Fruit Trees.—Mr. R. Curtis dealt with this subject in a short paper, in which he indicated that every gardener must spray if he would have clean fruit. Trees that were not protected from the ravages of fungus diseases, aphides, and other pests could not thrive and bear crops of good fruit. For fungoids and aphides, spraying should be done whilst the trees were dormant, or before much foliage had grown, as the solution used could then be much stronger than would be safe after the leaves had appeared. Aphides got their nourishment by sucking, and must be destroyed by contact with the spray, either by burning or suffocation. Tobacco wash, resin paint, or red oil were good for these troubles. Curl leaf of peach trees was a fungus disease and could be prevented by spraying with Bordeaux mixture as soon as the color could be observed in the flower buds. Arsenate of lead, a good strong solution for the first spraying, should be used for codlin moth when the petals had nearly all fallen. The spraying should be repeated 14 days later, and a third time a month after that. The later varieties of apples should be given a fourth spraying. He always sprayed export apples and pears a week before picking to secure the fruit from the ravages of small grubs, which might be missed in picking and spoil the fruit in transit. In the discussion which followed, some members considered that fruit tree pests were really a blessing, inasmuch as they resulted in good prices for good fruit, and the man who was willing to spray properly at the proper time benefited accordingly. Burgundy mixture was quite effective for curl leaf, was easily mixed, and was cheap.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Beetaloo Valley, August 11.

(Average annual rainfall, 18in. to 19in.)

Present.—Messrs. Burton (chair), Murphy, Ryan, Jacobi, Cox, Joyce, A. Bartrum, Woolford, Curtin (Hon. Sec.), and three visitors.

Cultivating and Manuring Orchards.—The Chairman read a paper, from which the following is taken :—" It is a good plan to plough or cultivate the orchard one way early in the season, to allow of the ground becoming well saturated, and to cross work it at an early date to keep it from setting. As warmer weather appears cultivate occasionally, which causes the weeds to decay in the soil, thus keeping the land in good heart. As the season advances the cultivator should be kept going, especially on warm days. This will soon result in the orchard being perfectly clean, with a nice loose soil, and assist in the retention of moisture. If summer rains fall, cultivate each way. Fruitgrowers should never allow their trees to suffer through lack of proper food. Some soils naturally contain a large amount of plant food, yet this cannot be expected to last for all time. Every crop removes materials in certain proportions, and these should be returned in the shape of manures. An occasional dressing of manure is of great assistance and materially aids in keeping the trees in a good condition. Special manures are also serviceable to make good the shortage in the soil which is caused by exhaustion of lime, potash, and other essential materials. However, the excessive use of manure, while conducing to strong growth and heavy crops, will cause a falling off in the quality of the fruit. Even soils that were originally rich may after a time become more or less exhausted and cease to give satisfactory returns without assistance in the form of manure. The period of the year at which manures are applied has a great deal to do with their value, and the value of a dressing is often reduced through it being applied at the wrong season, or when the soil is too dry to admit of its decomposition and assimilation by the roots. Fruit-forming manures, or such as are given to perfect healthy trees and to ensure good quality fruit, are given in spring or towards summer, according to the time of ripening ; on the other hand, under normal conditions, wood and bud-forming manures are best applied in autumn, before the ground gets cold or soaked with water. Systematic feeding of the roots is desirable in the late summer and autumn, as it keeps the immature buds from ripening by developing and plumping up the shoots. Stable manure and green crops are best ploughed in; nitrogenous and phosphatic manures should be harrowed in. The use of manure means healthy trees and vigorous growth, which develops the power to resist insects and other diseases. If the soil is worn out or deficient in humus, this must be supplied either by the liberal addition of farmyard manure or by the planting and turning under of leguminous crops, which, besides furnishing humus, supply the soil with a certain amount of nitrogen derived from the air. To ensure a good crop of legumes on a worn soil an application of kainit, lime, and phosphoric acid is necessary. Manures, such as potash and phosphates are suitable for application to the trees in the orchard, but as a rule the addition of lime or gypsum will render the addition of potash in any quantity undesirable. Gypsum renders the organic matter in the soil available for plants at once, therefore it must not be applied too freely, or it will cause a percentage to be lost by leaching." Mr. Joyce thought it advisable to apply all manures early in the winter. Mr. Jacobi recommended experiments with various manures.

Belalie North, June 14.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. P. J. O'Leary (chair), A. H. Warner, F. Gullidge, D. Smart, D. Fox, T. Dunstone, T. P. Scholz, W. Cummings (Hon. Sec.), and six visitors.

Feeding Farm Horses.—In a paper on this subject Mr. Dunstone described the method he adopted for feeding horses. Chaff and bran were given in the morning, one hour being allowed for feeding; from one and a half to two hours being allowed for the mid-day meal. Long hay was fed last thing at night. Green feed or boiled linseed tended to purify the blood and keep the animals in good health. One pint to one pint and a half of the latter was sufficient for the feed. Regularity in feeding was essential.

Care of Farm Implements.—Mr. A. H. Warner dealt with this subject in a short paper, in which he advised the careful cleaning of dust and oil from implements and machinery before they were put away in the sheds. A good coat of paint had a beneficial effect on the wood and iron work.

Belalie North, July 12.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. P. J. O'Leary (chair), A. H. Warner, P. and D. Fox, J. Gullidge, T. Dunstone, T. P. Scholz, and 10 visitors.

Home Life on the Farm.—An interesting paper written by Mrs. W. Cummings was read by Mr. Warner. The writer pointed out that the management of a farm entailed the exercise of considerable tact. Improvements gleaned from the inspection of neighboring holdings, together with the experience of personal experiments, should materially assist in making conditions on the farm more satisfactory. Surrounded as it was by the beauties of nature, the farm life should be the best and brightest of all; but this was not likely to be the case where the farmer thought too much of money-making, or where lack of experience made the burden heavy. The home should be made attractive. Creepers, trees, flower and vegetable gardens should be planted. At intervals of five years the house should be painted and renovated. Entertaining books, music, and similar attractions should be provided. The farmer should give his son an early insight into the whole business of the farm. He should make him a partner in the concern as soon as the boy was old enough to appreciate the relationship. There would then be less inclination on the part of the son to abandon the land for life in the city.

Crystal Brook, June 21.

(Average annual rainfall, 15·62in.)

Present.—Messrs. M. P. Pavy (chair), W. J. Venning, W. Hutchison, G. Davidson, I. Teakle, G. Miell, A. J. L. Wilson, G. Gum, H. and S. Billinghurst, A. E. S. Clarke, G. Sargent, T. L. Kelly, A. E. Cooke, G. A. Solomon, R. Heaslip, J. B. Greig, J. H. Hill, W. W. Lovelock, A. J. Dennis, H. Growden, J. Pridham, M. Weston, A. Macdonald, B. Weston, H. Sutcliffe, W. W. Robinson (Hon. Sec.), and one visitor.

Short Weights in Super. and Twine.—The following paper was read by Mr. R. R. Shaw:—" One of the first principles laid down by business men is to get an equivalent for money expended. Most commodities are sold by weight or measure, or so much for the complete article. The ordinary purchaser going into a store pays for the article he buys at a price mutually agreed upon by the seller and buyer. When a farmer sells the produce of his labor the buyer invariably checks the weight of same and makes pretty sure that he gets the full value of that for which he pays. This being so, the farmer has an equal right to insist upon getting the full value of that for which he pays—but does he ? Taking the first of several articles, *i.e.*, binder twine. This is supposed to be sold by weight, each ball weighing about 5lbs., with 12 balls to the bale, equalling about 60lbs. The weights of these have been checked in scores of cases after being taken to the farm, and have been found 2lbs. to 4lbs. short after the sack or bale is removed. Last season there were 714,766 tons of hay cut in South Australia. Assuming that all, or nearly all, of this was cut by the binder, 23,825 bales of binder twine were used; estimating one ball of twine for 2½ tons of hay. A shortage in weight of 2lbs. on each, which is well within the mark, gives a total of 47,650lbs. at 7d., which the farmers paid for, but did not get. It is futile for the vendor to say that it loses weight by keeping. If such is the case, then an allowance should be made for the shortage on each bale or number of bales. They should be weighed out on delivery and payment made for the actual weight, less the sack enveloping same. Another article used very extensively on the farm is superphosphate. The present system is very unsatisfactory in regard to weights, as, unless a farmer gets his consignment separately with a guarantee of weight, he is not sure of what he is getting. Where farmers have checked the weights of a few bags and found them short, the agents have assured them that if a few bags are short weight there are others overweight, which will make up for the deficiency. A farmer in this district weighed a few bags of his consignment and found that if they all were the same weight he would have had half a ton short delivered. It seems just as reasonable for the agent to take the farmer's word for the weight of his load of wheat as for the farmers to take the agent's word for the weight of the super. he delivers. Super. should be weighed out upon delivery, the same as any other commodity, and for preference over a public weighbridge, which should be installed at every railway station which is the outlet for big wheat-producing districts. Another matter that I should like to draw attention to is the general dissatisfaction expressed by those who send eggs and poultry to the Adelaide salesmen. The preponderance of evidence and experience of those engaged in this business is that, in the case of eggs, there is far too much docking for breakages; in several cases there has been amounts knocked off the account sales for broken eggs when it has been known that the packages were exported to the other States without being opened or examined. I do not impute dishonesty, I put it down to slack business methods on the part of the vendors, and apathy on the part of the farmers for not taking concerted action to get matters rectified. In the case of super., the vendor has to submit a sample for analysis from bulk. This is published for the benefit of the purchasers, and this standard has to be maintained or the vendor is liable under the Fertilisers Act. This Act should be amended by requiring the addition of a guaranteed weight in each bag. The same argument applies to binder twine and all other articles used extensively on the farm, as the narrow margin between profit and loss in growing wheat alone demands that there should not be any leakage in short weights." In discussing the subject, Mr. M. Weston said that wrappers were purchased as binder twine, in the same manner as bags were sold as wheat. No trouble would be experienced with short weight in colonial-made or re-bagged super. Mr. Clarke said short weight in most cases was due to evaporation, but in the case of binder twine the decrease in weight was concurrent with an increase in length. Super. weights were generally correct if there were no leakage. Mr. Heaslip pointed out that whilst the wrapper on binder twine was practically useless, wheat sacks could be sold at good prices secondhand. The tare of railway trucks was unreliable, as they frequently contained a quantity of sulphide, &c., and the weather conditions caused variations. Mr. Munday had noticed a variation of 10lbs. in the weight of super. Mr. Venning thought twine and super. should be weighed on delivery by the agents. He had found as much as 10lbs. short weight in a bag of super. and 3lbs. or 4lbs. in a bale of twine. Mr. Sutcliffe thought eggs and fruit should be graded and open to view in the markets. Mr. Hill had found a variation of weight in the individual bags in a line of super., but the total weight was correct. Mr. Solomon read correspondence from the manufacturers with regard to the practice in operation at their various works for weighing the super. for delivery. It was weighed in the bags on an automatic Avery scale, 4½lbs. overweight being put into each bag as allowance for the bag and shrinkage, the actual gross weight of each being just over 191lbs During the course of the day the weights of individual bags were continually checked on a platform Avery scale, and in most instances it was found that the automatic scale was slightly in excess, this, no doubt, being due to the automatic cut off not being sensitive enough. In no instance had they found the automatic weigher under weight. The correct weight was in the bags when they left the works. Any loss was, no doubt, due to rough handling when the fine super. would pass out through the pores of the bags, and to shrinkage. In the case of super. bagged late in December, which no doubt contained 10 per cent. of moisture, and delivered to outports, the hot weather most likely caused a loss of weight by shrinkage. As this shrinkage went on through loss of moisture, so the phosphoric acid contents increased, and although the weight might not be in the bag the grade of the material contained therein would be higher. Thus the farmer was compensated for the loss in weight, for he was obtaining a much higher grade manure than he was guaranteed. Super. bagged at the works and containing 10 per cent. moisture and 37 per cent. water soluble tricalcic phosphate might be delivered and held in store for, say, three months during hot weather. At the end of this time, if an analysis were made, it would be found to contain, say, 4 per cent. moisture, but the water soluble tricalcic phosphate would be 39·4 per cent., as against 37 per cent., and the bag would be found to have lost through shrinkage 11·46lbs., equivalent to 137½lbs., per ton. Thus, while the weight might have decreased through shrinkage the grade of manure had considerably improved.

Mount Bryan, August 11.

(Average annual rainfall, 15·81in.)

Present.—Messrs. Trallagan (chair), Wardle, Hatherly, Phillips, Jefferies, Nutt, and Hatherley (Hon. Sec.).

Poultry —In a short paper on this subject Mr. Phillips said that for the profitable production of eggs regular feeding was essential. He had found the Brown Leghorn a good fowl for egg production and table purposes; whilst it was not equal to the White Leghorn for laying purposes it was much better for the table and produced more eggs than the Wyandottes. They kept in good condition and stood the cold winter experienced in this district well. The practice he adopted was to change the breeding stock every year, procuring eggs from proved strains, rearing chicks the following year from two-year-old hens crossed with one-year-old male birds. The business could not be profitably carried on unless good reliable stock were kept.

Port Germein, August 9.

(Average annual rainfall, 12·84in.)

Present.—Messrs. Hackett (chair), Holman, Carmichael, Teasdale, Stone, Deer, Hillam, Glasson, Head, McDougall, Crittenden, and Stewart (Hon. Sec.).

Poultry on the Farm.—Mr. H. Crittenden read a paper, in which he said, "The average farmer has a lot to think about, and in the majority of cases he views his poultry as a matter of little importance. In the first place he gets a few fowls to provide sufficient eggs for use on the farm and a bird occasionally for the table. He is generally fairly particular in his selection for a start, but, of course, he has only a few fowls and allows them to roost on a tree close by, because it would not pay to put up a house for them, or he has not the time. These fowls do very well. They have come to a new place, and they have all that nature demands. In some out-of-the-way corner they bring out their chicks. This continues for years and the farmer finds that he has done well by buying those few fowls. They have become a big flock, and they have kept him in eggs, and he has sold hundreds of dozens. But at last disease sets in and he finds them dying fast. After the disease has taken about half of them he finds those left are a miserable lot, and are falling off in their egg production. Compare his 30 fowls with 30 fowls 12 months old kept in the correct way, and what do we find? Just this: that these fowls are laying about 25 eggs per day and bringing in a good return for their food. The farmer has done wrong in many ways. He took the fowls on new country in the first place, and they did well, because there was plenty of natural herbage. This he has neglected to keep up. He has cleared away all the surrounding trees which gave his poultry shelter, and left them to, perhaps, the dry limbs of a dead tree. He has allowed his stock to breed in year after year. Perhaps he is left with a lot of the old hens. This is simply because he has neglected his yard. He says they do not pay to look after. He should go to his starting point again, sell out all his old stock, select a new lot, and keep young healthy birds, and they will repay any work that he puts into them." Mr. Hillam agreed that the breeding of poultry should be carefully controlled by the farmer. Mr. Hackett considered lice and tick the source of considerable trouble with the fowls.

Port Pirie, August 2.

(Average annual rainfall, 13·21in.)

PRESENT.—Messrs. J. Greig (chair), W. Munday, T. Johns, F. Johns, W. R. Wright, T. Kirchner, A. Bond, and A. M. Lawrie (Hon. Sec.).

HARVESTER *v.* STRIPPER.—In a short paper on this subject, Mr. F. Johns said the harvester should be driven by a person who had a direct interest in the crop being taken off, as, unless every care and attention were paid to the machine, a dirty sample would be secured, and grain would be lost over the tail piece. For the person who was cropping a fairly large area it would be found better to have one stripper in addition to the harvester. It was essential for him to keep a winnower for the purpose of cleaning the seed wheat, and the stripper could be used for reaping any particular variety of wheat being grown from which the best cocky chaff could be secured. The harvester worked best on level land where the speed of the machinery was maintained, but the stripper could be used on sandy rises and in such places where the use of the harvester was not advisable. Mr. Kirchner favored the use of the harvester, on account of the saving of labor which it effected. Mr. Munday thought the stripper would be more used in future, as the cocky chaff saved was coming to be recognised as a valuable standby. However, the harvester did good work in a heavy crop and any wheat that had gone down or was tangled, but oats and lighter weed seeds were distributed by means of this machine. ' Messrs. T. Johns and Wright preferred the harvester, but the Secretary advised the use of the stripper on rough stony land.

Redhill, August 26.

(Average annual rainfall, 16·79in.)

PRESENT.—Messrs. W. Pengilly (chair), D. and E. Steele, F. and F. A. Wheaton, Kelly, Stone, McAvaney, Potts, G. Button, P. H. Wheaton, Treloar, Holmes, Coffey, A. Dick, J. J. and W. Haynes (Hon. Sec.), and seven visitors.

HOMESTEAD MEETING.—The homestead of Mr. M. M. Coffey was visited. This constituted one of the best improved farms in the district. The convenient laying out of the stables and outbuildings was much admired. The crops were looking well, considering the season, and the experimental plots provided a matter of interest. A harrows-sulky, so affixed as to slide from one side to the other as the horses turned the corners, and which was designed by Mr. Coffey, was thought very useful.

NORTHERN BRANCHES CONFERENCE.—Mr. E. Steele presented a report of the proceedings of the Conference of Branches held at Saddleworth. Mr. F. A. Wheaton agreed with the remarks of Professor Lowrie with regard to the breeding of lambs. Mr. Stone preferred the first cross, and some members thought it would be necessary to resort to the second cross for fat lambs. Mr. D. Steele favored the Lincoln, and had bred to the third cross, and secured good lambs. Mr. Pengilly considered the Shropshire cross the best shaped lamb. Good feed was essential.

Spalding, August 15.

(Average annual rainfall, 20·25in.)

PRESENT.—Messrs. E. E. Gill (chair), Jones, Pluckrose, Ryan, McLeod, T. J. Preiss, J. Preiss, A. Howley, P. A. Gill, Sanders, S. Hennessy, G. Page, Work, Marrow, D. A. Campbell (Hon. Sec.), and three visitors.

VALUE OF LIME IN AGRICULTURE.—The following paper was read by Mr. A. B. Jones:—"The study of this subject is now occupying the attention of scientific investigators and practical agriculturists in different parts of the world. Until now the data available from experiments carried out under Australian conditions has been very limited, but, as the results of very complete field tests now being undertaken by the Victorian Agricultural Department become known, they will probably create an interest among farmers and provide a working hypothesis from which to commence operations. With my limited experience in these parts I cannot express an opinion on the likely need, value, or effects of lime, and, as previously remarked at these meetings, 'no hard and fast rule can be laid down for the district,' indeed, I will go further and say 'no hard and fast rule can be laid down for any particular farm.' Just as a few years ago the value of superphosphate was practically unknown to the agricultural community, so to-day lime stands in that position; although, paradoxically, lime was probably the first of the mineral substances applied as a dressing to the soil, and I venture to think that in a few years' time, and as the result of experiments now being undertaken, that an application of lime to the paddocks will come to be recognised as imperative as an application of superphosphate. On some of the private-owned railroads of America, and on the public railways of New Zealand, lime is carried at a loss, thus showing that its value is recognised in increased production. The soils of Australia, taken in general, are deficient in lime—the average percentage of inland soils reaching somewhere about 9,000lbs. per acre, about half the quantity considered by Prof. Hilgard (a noted American authority) to be necessary for a fully productive soil. Lime, although one of the principal essential elements of soil fertility, is not usually regarded as a manure—the value of its addition to the land is generally considered in a chemical, physical, or bacteriological sense. Its chemical effect is to assist in liberating the plant food contained in certain insoluble compounds in the soil, and the 'sweetening' of land that has become acid or 'sour' from the continued use of phosphate in the form of superphosphate. The physical effect is most marked by its action on heavy clay lands—the addition of lime to these soils renders them more friable and porous, thereby assisting ærration, gives them power to absorb and conserve more moisture, and facilitates the working and cultivation of that class of soil. Lime greatly assists in the decomposition of organic matter applied to the soil or naturally present therein, and thus is of great value in supplying humus—probably the most valuable soil constituent. As the result of elaborate experiments carried out at the Iowa Experimental Station the addition of lime was found to have a very beneficial effect in increasing the number of bacteria present in the soil; and the conclusions arrived at were, 'that the application of lime to soils will render more available the plant foods in soils and fertilisers, thereby improving crop conditions, and that an application of lime is practically equivalent to the direct use of nitrogen, phosphoric acid, and potash.' These results are equally applicable to the soils of Australia—whether or not the practice will be found payable on any particular farm in this district I leave to the owner of that farm to find out by experiment. The value of a heavy dressing of marl (a form of lime) given to certain paddocks at the Rothamstead Experiment Station, England, more than a century ago is still evidenced by their productive capacity compared with adjoining paddocks not so treated. How are we to know when our land requires liming ? There are certain simple tests that can be made, but the results are not an infallible guide. One method of testing is to procure a small quantity of soil and treat it with hydrochloric acid, *i.e.*, spirits of salts. If an effervescence occurs it will reveal the presence of lime; no action taking place will probably mean a deficiency. One may often detect a deficiency of lime by the growth of certain kinds of vegetation, such as sorrel—this and certain other weeds will flourish in a sour soil. The strong growth of clover will usually denote a sufficiency of lime; and it may here be remarked that lucerne and other leguminous plants require large quantities of lime to be present in the soil for their development. Calcium oxide, which is the chemical name for lime, is found under various names, such as limestone, marl, quicklime, slaked lime, gypsum, &c.; which of these is most profitable for use depends mainly on proximity to limestone deposits. All these forms are not of the same value for agricultural purposes. For instance, one ton of quicklime will contain one and three-quarters times as much pure lime as that weight of ground limestone, and three times as much as one ton of gypsum. Certain of the commercial fertilisers on the market contain a fair proportion of lime—phosphatic guano containing about 40 per cent. and Thomas' phosphate 20 per cent. pure lime. The lime in these cases is procured for practically nothing. I might mention that lime in the form of gypsum is of no value if intended for the purpose of sweetening sour land, as it is already in combination with an acid, and therefore will not unite with and neutralise the acids of the soil. Quicklime is the most useful form for decomposing organic matter to form humus. There are different systems employed for dressing the land—one method is by distribution by means of the ordinary drill. This, of course, demands that the lime should be in a finely pulverised form, and only limited quantities can be applied at the one operation. A handy attachment can be made for working at the rear of a cart or wagon, and this will allow of heavy dressings. Special machines may be purchased for the work, and I believe they may be purchased up to 10ft. in width, so should greatly facilitate the operation. The dressing should be given to the fallows some time previous to seeding, except in the case of ground limestone, which may be applied at any time. I might add that lime should always be applied to the surface and harrowed or lightly scarified in—not ploughed in, as it has a tendency to sink in the soil and be carried off in the drainage waters. Heavy dressings, as much as 3 tons per acre, are beneficial to very heavy soils rich in organic matter, and the old custom in other countries has been to make heavy applications at long intervals. The present day idea is smaller dressings at shorter intervals; and again I must state that the quantity, if any, that can be profitably made use of can only be ascertained by actual and careful experiment, and it must always be used in a regular system of manuring with phosphates and the addition of organic matter. There are certain precautions to be observed when using lime for agricultural purposes. I have previously stated that it supplies humus by the decomposition of organic matter, and it is equally true that it is a robber of that vital necessity; therefore, as I have just stated, on most soils, with the generous use of lime, some system of supplying humus is imperative. I again repeat that line will not dispense with the use of phosphates. Although most people will admit the efficacy of a dressing of lime they will probably object to it on the score of cost and labor; but in these times of high land values it is essential that we should make the very best use of limited areas, and if the addition of lime to the usual course of a dressing of phosphate is going to prove profitable it will be to the advantage of farmers to make use of this element to assist them in maintaining the fertility of their land and securing higher yields."

Whyte-Yarcowie, July 21.

(Average annual rainfall, 13·91in.)

Present.—Messrs. G. F. Jenkins (chair), McGregor, McLeod, Wittwer, J. Walsh, F. Hunt, F. Pearce, J. R. Mudge, C. Siebert, G. D. and W. Mudge, F. H. Lock, E. J. Pearce (Hon. Sec.), and two visitors.

Bulk Handling of Grain.—In discussing the subject matter of the paper read by Mr. Lock at the June meeting (printed on page 1423 of the July issue), Mr. McGregor said that whilst there was a great lack of disinterested information on this subject, he believed the bulk system of handling grain would be an improvement. Mr. Lock read an extract from the report of the Royal Commission on the Marketing of Wheat, which showed that the elevators in Canada were largely owned by the railway companies. That the cost of an elevator in America was about 2½d. per bushel of capacity, and that there were sometimes as many as six elevators in one railway yard. Some small ones were of 20,000bush. capacity. The only shipment of bulk wheat from Australia he had experience of was one of 1,500 tons from Sydney. This was discharged into elevators at Liverpool, and was from every point of view satisfactory. Some half a dozen of the leading millers in England thought so highly of the elevator system that they had erected elevators at their mills, and even had suitable railway wagons constructed to rail their own grain on company-owned railways. He thought it was quite time the matter was taken up in Australia. Mr. Wittwer was of opinion that the chief difficulty at the outset in introducing the system would be in dealing with the wheat on the farms. How were they going to manage in the harvest-field? They were always anxious to remove the crop in the shortest time possible, and a farmer could not always have the plant and labor necessary to carry the wheat off the field as fast as it was reaped. The Hon. Secretary read a short extract from a New South Wales paper, which showed that the mother State was alive to the advisability of substituting a more up-to-date method of handling grain for the one now in use. An expert had been brought from America and had been over all the railways of the State, and was conferring with the Railways Commissioner with a view to introducing the system. This expert was satisfied that the introduction of the bulk system would mean a great saving to both producer and consumer. The speaker was satisfied that the system was a superior one, and although, perhaps, for a time, in most cases farmers would still use cornsacks for transport purposes to the elevators, 100 sacks would suffice where now 1,000 were required, and these could be of superior quality. The Chairman thought this State was handicapped to a considerable extent by the scattered nature of the agricultural areas and the number of ports at which wheat was shipped. However, he would like to see the matter taken up by the farmers and thoroughly thrashed out. Mr. Lock, in replying, said that if this matter, which was undoubtedly in the air, was to materialise, the farmers themselves must take the initiative; it was to their advantage, and they would probably find that they were up against strong interests that were vested in the present system.

Yongala Vale,

(Average annual rainfall, 13in. to 14in.)

Present.—Messrs. T. Keatley (chair), J. Lloyde, W. Laubsch, F. Miller, E. Cooper W. Edson, A. Jamieson, sen., B. Webb, G. Lloyde, J. Barker, G. Keatley, G. I'Anson, G. Battersby, C. Fowler (Acting Hon. Sec.) and two visitors.

Fallowing.—In a short paper on this subject, Mr. W. Laubsch said stubble should be burnt as soon as possible, and the ground broken with the cultivator; providing there was a fall of rain ploughing should be done early, and harrows should follow the plough to encourage a growth of weeds. The land should be cultivated once before or during hay-making, and, in the event of heavy rain, during harvest. On no account should the weeds be allowed to seed. The ground should be worked in March and again at seeding time in May.

Vegetable Parasites.—Mr. E. Cooper contributed a paper. The application of boiling water to grub-infested cabbages or cauliflowers, he said, would destroy the grubs without injuring the plants. Kerosine emulsion was used for this purpose in the United States of America. Slaked lime (four parts) and tobacco dust (one part) constituted a very effective dry spray, which remained on the plants for a considerable time, and destroyed insects which attacked the leaves.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Angaston, July 25.

(Average annual rainfall, 22·25in.)

Silver Jubilee.—The silver jubilee of this Branch was commemorated by a public gathering, held in the institute hall. A large number of visitors, in addition to members, attended. The Hon. Secretary (Mr. E. S. Matthews) gave a résumé of the work done by the Branch since its inception in 1888, and made eulogistic reference to the support it had received from a large number of influential gentlemen resident in the district who had been members during the years of its currency, and some of whom were still on the attendance roll.

Blyth, August 15.

(Average annual rainfall, 16·46in.)

Present.—Messrs. A. L. McEwin (chair), J. S. McEwin, P. H. Zweck, J. J. Clarke, W. and J. Pratt, M. and T. Williams, A. A. Schulze, W. J. Ninnes, R. Buzacott, C. Lehmann, W. H. Best, F. T. Pedler, J. F. Bishop, H. Neumann, J. T. Harmer, A. Dunstone, J. R. Evans, A. D. Pedler, H. W. Eime (Acting Hon. Sec.), and three visitors.

Care of Brood Mares.—A paper was read by Mr. C. Lehmann, dealing with the above subject. At the mating season, the writer said, mares should not be worked too hard. When visibly in foal they should be kept in good condition without being allowed to get too fat. Record should be kept of dates, so that proper arrangements could be made for foaling. If possible, at this time, mares should have a small paddock to themselves near the house. The writer then proceeded to describe what assistance might be given at parturition. Continuing, he said that in some instances it was necessary to teach the foal to suck, and failing this, to milk the mare into a warm jug and induce the foal to get a taste for the milk. He did not believe in working mares after foaling if it could be avoided, but he would work them right up to that time with discretion, for exercise was absolutely necessary.

Clare, July 18.

(Average annual rainfall, 24·30in.)

Present.—Messrs. J. Dux (chair), J. Scales, A. Hill, H. A. Hanna, B. Lloyd, M. L. Nolan, F. W. H. Lee, F. J. Knappstein, J. H. Knappstein, F. Pink, D. Menzie, W. Pattullo, and P. H. Knappstein (Hon. Sec.).

Poultry-Breeding and Feeding.—The following paper was read by Mr. F. J. Knappstein:—"The poultry industry has advanced by leaps and bounds since the Government has taken an active part in it. Thanks are due mostly to the expert (Mr. Laurie). Poultry-breeding requires patience and perseverance, coupled with cleanliness and regularity. The first essential is a nice site for yards, with plenty of space. The house should be built of iron—the uprights angle iron, and roof and walls galvanized iron. Tick is not then so troublesome as it is on wood. The houses should have plenty of floor space, they can then be used as scratching pens on cold, frosty mornings. They should face the east, if possible; the perches should be round and all one height, because fowls have a tendency to crowd together on the top perch, which is not healthy. Make a nice hard floor, so that it can be cleaned easily. The yards should be on a slope if possible, so that they will drain well. A yard 38ft. by 10ft. will be ample room for from six to eight birds. Plenty of water is necessary. The selection of stock is the main point, and if people only thought a little before buying their birds there would not be so many failures. I do not favor buying a pen of fowls that have broken a record or anything like that, because those fowls have taxed their vitality. Purchase fowls from a breeder who has proved himself in public tests, because a breeder who has done well in tests knows a bad fowl from a good one; and, as a rule, he sells out his inferior birds before the breeding season comes on. This applies both to laying and table fowls. The breeds I favor fo laying are the Leghorns (both white and brown), Black and Buff Orpingtons, Silver Wyandottes, and Langshans. The White Leghorn is absolutely the best. Some people do not like these Mediterranean breeds on account of being non-sitters, but I like to see a yard with White Leghorns or Black Orpingtons. The Black Orpingtons are good layers of brown-shelled eggs, and are very consistent if bred from good stock. The same thing applies to Buff Orpingtons, Silver Wyandottes, and Langshans. The Leghorns are the most consistent of the lot, and have produced 250 and more eggs each a year. They are hardy, and not subject to diseases like some of the other breeds. Minorcas lay a very large white egg, but are not very consistent. For table fowls a good Indian or Malay game cock crossed with Buff Orpington or Faverolle hens is best. Birds of the block type, not long in the legs, are required. Table fowls should have white or yellow legs, as they look cleaner and sell better. An Indian-Buff cross is worth from 2s. 6d. to 3s. 6d. at six months old, even earlier if they are forced. Some people like the Langshan-Buff Orpington cross, but it is too leggy and the legs are black. For hatching chickens I prefer the incubator to the hen. Where people only go in for a few fowls they should always keep some of the heavier breeds I have just mentioned. It is hardly worth while buying an incubator in the case of a man who only keeps about 20 fowls, but for anybody who is going in for poultry on a large scale an incubator is a necessity. The machine is very simple to work; it only takes as long to turn the eggs and trim the wick as it does to feed and water a hen. All sizes—30, 60, 100, and so on up to 500 eggs can be purchased. When sitting a hen always make a nest on the ground in some quiet and dark place, if necessary, away from the other fowls. Put the hen down in the evening, after putting in some straw and sprinkling the nest well with insectibane or some other insecticide, with about two or three dummy eggs under her, and cover her until next evening, then give her the eggs if she is willing to sit. Never put food and water too close; make her come off the nest to feed. A sitting hen should always be fed on grain; under no consideration give her mash. It takes from 20 to 21 days for eggs to hatch. Chickens of laying breeds should be fed from the start on small grain, such as hemp seed or crushed wheat mixed with a little chaff, to encourage them to scratch. Greenfeed chopped up fine is very good for them. Keep them on the small grain till they are about a month old, and then feed whole grain, such as wheat, oats, barley, and buckwheat. When they are between 6 and 7 months old give them mash in the morning, green feed at mid-day, and grain at night. A mash is made up of one part bran and two of pollard, with a little meat meal mixed in with it. It can be fed warm on a cold morning. Never give fowls sloppy food. Never feed in a trough; it cannot be kept clean. Have the mash so stiff that as it falls from the hand to the ground it will break, and feed on clean ground. Have plenty of grit, such as small sea shells, broken up bones, lime rubbish, and gravel where the fowls can get at it; also some fine charcoal. Too much meat meal will result in loss of feathers and general ill-health. The table fowls can be fed from chickens on mash and small grain. Do not give mash every feed, but once a day. When the fowls are ready to top up confine them in a small space. Two weeks should be sufficient in which to bring them to prime condition. If kept after that they cease to improve, they again immediately lose flesh. The best food is bran and pollard, with a few peas for a change; always give it hot. The fowls may be kept in well-ventilated coops, being fed three times a day, and allowed plenty of gravel and water, except for the last week; then stop the gravel. The coops, of course, must be kept clean, and should be small enough to prevent the fowls turning round. They should be littered with clean straw and never allowed to get foul. If instead of water, their drink is skimmed milk they will do better. It is not wise to dabble with several varieties. Select one or two. The aim is to get experience, no one can succeed without this. Be sure that plenty of dust for bathing, such as wood ashes, is supplied at all times. It is a great remedy against lice, to which fowls are especially liable. This, with plenty of shell grit, sand, good clean water, and liberal feeding will ensure success, both in eggs and chickens. Do not crowd the house; see that everything is kept thoroughly clean. Mating requires a great amount of knowledge. The hens of activity, bright in comb, sparkling in the eye, and showing vigor, and often seen in the nest box, should be bred from. The beginner can easily detect the best from his limited number. The male bird should be purchased from a specialist. A good breeding cockerel is always worth a guinea. He should be active and alert, and show good standard points of his breed. The eggs will not be fertile for eight or 10 days. Of the heavy breeds, eight hens to a cockerel is sufficient; in the light breeds anything from 10 to 20 hens can be given with good results. Chickens hatched out by an incubator must have every attention. Nature has provided the chick with its food for three days after hatching. The nearer one can get to that food the better the results. For the first week feed on coarse oatmeal soaked two hours before using; a trough containing bran and pollard may be left after the first week. Green food should be fed once a day. Chop this up fine and feed at noon. As soon as possible the sexes should be separated, this can be done at the age of 2 months." Mr. Knappstein mentioned that it was the desire of the Poultry Expert to establish in the future laying competitions the regulation that each pen must contain 10 hens instead of six hens, as it was at the present. This was not fair to the smaller breeders, as they could not spare 10 hens from their yards. He maintained that it was helping the larger breeders to increase their number, and asked this Branch to take the matter up in the interests of the small breeders in this district. Mr. Menzie said poultry-breeding looked a good paying proposition on paper, but he did not know whether it was so good in practice, as he had heard of a few failures. Mr. Nolan thought poultry were profitable up to a certain extent, but when a man went in for it on a large scale and had to employ labor, and purchase a costly plant, it would swallow up the profits. Mr. J. Scales said his experience with poultry was that they were not profitable. He could never keep them out of the horse's mangers from scratching the horse's fodder, to its detriment.

Clare, August 15.

(Average annual rainfall, 24·30in.)

Present.—Messrs. J. Dux (chair), W. J. Maynard, F. J. Knappstein, F. Pink, F. J. Gerteau, G. Victorsen, A. Dunstan, B. Lloyd, A. Hill, J. Berridge, H. Hanna, W. Patullo, C. Pink, P. Pascoe, F. Hicks, M. L. Nolan, C. Jarman, C. Neate, J. H. Knappstein, and P. H. Knappstein (Hon. Sec.).

Black Spot on Vines.—In reply to an inquiry as to the best treatment for black spot on vines, the following was recommended:—7lbs. sulphate of iron, 1 pint sulphuric acid, and 2galls. water, mopped on the affected parts.

Care of Implements.—Mr. H. A. Hanna read a paper on this subject, in which he urged the necessity for proper shed accommodation for farm implements. A coat of boiled oil should be applied every two or three years, and the appearance of the plant was improved by the addition of paint. Continuing, the paper read—"The cones in the manure-box of the drill should be thoroughly cleaned, also dirt or grease that has gathered about the oil cups and bearings, as there is nothing that wears out a bearing more quickly than a mixture of oil and grit. Having cleaned all the parts, they should be oiled to prevent rust. This overhauling applies to the binder, which should be cleaned and the knives sharpened and then oiled, so that instead of rusty knives, one has them clean and sharp to commence operations. The ploughs should have their share of attention. To prevent rust on mouldboards, smear them with grease, and there will then not be the inconvenience of stopping every few chains on account of the boards clogging with dirt. Broken or worn out parts should be replaced at once. The habit of leaving the cleaning and repairing until the machine is wanted often means that it is not repaired as it should be, because the harvest or seeding has come with a rush. Consequently worn parts break and leave the farmer stranded in the midst of work, causing loss of valuable time."

Friedrichswalde, August 16.

(Average annual rainfall, 18in. to 19in.)

Present.—Messrs. F. Heintze (chair), R. Marlow, F. W. Duldig, T. Pfitzner, G. Grope, J. Heintze, F. W. Schütz, P. Goodfellow, Coombe (Hon. Sec.), and five visitors.

Horses and Harness.—The following paper was read by Mr. F. W. Duldig:—"It is essential that horses should be well cared for in every respect, and that their harness should fit. It is advisable, in buying harness, to see that the material is good throughout, even if it costs a few shillings extra. In the case of winkers, it is necessary that the eye flaps should be sufficiently high to prevent the horse seeing over the top. The bit should be comfortable in the horse's mouth; if it is too tight it is irritating to the horse and to the driver. If the winkers are too long there is a danger of the horse taking the bit between his teeth. Every horse should have its own collar. It is advisable to buy a pipe collar, and one of good material, as the better class appears to fit better than the cheaper. They also keep their shape better. The collar should be well rounded at the top, to avoid pinching the horse's neck. When working a drill, or binder, or any implement which requires the horses to carry weight on the neck, they will almost invariably get a sore neck if the collar is narrow at the top. I think the angle steel pattern of hames the best, as these fit closely into the groove of the collar, and very seldom move. In most cases it will be found that the hame hook is too low, and it will pay to take the hames to the blacksmith and get this fastened higher up. Backbands should be on the chains, as these keep the direct pull of the horse on a level with the shoulders, and take a certain amount of weight off the horse's neck. There is less risk of the horses getting their legs over the chains. Oil, a few stitches, and copper rivets will greatly assist in lengthening the durability of harness. If slow and fast horses are to be worked in the same team, the fast animals should be tied back. The best method is to fasten a strap, with a strong ring attached, through both bit rings and under the jaw. Another strap should then be fastened to the next horse's rein ring on the hames through the ring under the horse's jaw, and attached to the rein ring on the harness of the horse on the other side. I prefer working horses tandem as much as possible, as a lot of heavy swings are abolished, and the horses are not so likely to tread on each others hoofs. I do not favor equalisers for the leaders, as the body horses have no opportunity to ease the collars on their necks. Three or four strong links do just as well." In the discussion which followed, Mr. J. B. Coombe thought that each horse should have a collar fitted, and it should be tight into the neck when the animal was working, so that the weight of the pull would be borne by the muscles and not the bone of the shoulder. He also favored the old-fashioned long hames, as with these a more even pressure all round the collar could be obtained. Mr. P. Goodfellow and others believed in using equalisers for the leaders in tandem teams, as they would then be pulling by leverage and not a dead pull, which was certainly easier for the horses.

Julia, August 13.

(Average annual rainfall, 18in. to 19in.)

FIELD TRIAL.—The Branch reports having held a successful field trial of stump-jump implements, near Hampden Siding, on August 13th, on the Anlaby Estate property, by kind permission of the manager, Mr. De Lucas. Fine weather favored the undertaking and a good attendance was the result, fully 200 people being present. The trial field consisted of both good and rough land, which gave the implements a splendid chance to demonstrate their respective merits. The entry list, considering the season, and also that this was the first trial undertaken by the Branch, was satisfactory; there were 18 entrants. A field committee consisted of Messrs. T. Brown, R. W. Rowell, J. Dunstan, T. Carter, and A. Pfitzner, and five teams of horses were supplied by members of the Branch. The judging was done on points, and the judges, Messrs. T. Prior, D. Heaslip, W. Poulden, J. Jaffer, and, J. T. Freeman were kept very busy. The points awarded the respective exhibits by the several judges were totalled and the sum divided by five to secure an average award of points; on this the results were determined. Results: Ploughs—first, Clarence Smith, Limited, Ardrossan, 83·80 per cent.; second, Jansen Bros., Eudunda, 82·20 per cent.; third, H. H. Prior, Marrabel, 80·00 per cent.; other competitors, 79·40 per cent., 68·40 per cent., 56·00 per cent. Cultivators—first, H. W. F. Klaebem, Eudunda, 89·90 per cent.; second, Vogt Bros., Kapunda, 80·60 per cent.; third, Linke Noack, Freeling, 79·80 per cent.; other competitors, 79·20 per cent., 78·40 per cent., 76·60 per cent., 74·80 per cent. Skim ploughs—first, Clarence Smith, Limited, Ardrossan, 77·20 per cent.; Linke Noack, Freeling, 74·80 per cent. Harrows—first, H. H. Prior, Marrabel; second, C. Morick, Point Pass; J. G. Traeger, Hamley Bridge.

Julia, August 16.

(Average annual rainfall, 18in. to 19in.)

PRESENT.—Messrs. T. Prior (chair), A. Pfitzner, D. Heaslip, C. Nash, W. Hall, J. Dunstan, R. W. Rowett, G. Gaerth, W. H. Neal (Hon. Sec.), and two visitors.

Care of Working Horses.—Mr. D. Heaslip read a paper, as follows :—" Colts should be ready to work at 2½ years old, but should be worked only for a short time at first, to allow their shoulders to get used to the collar. In fact, any horse should only be worked a short time for the first two or three days after spelling. Sore shoulders are often caused through fast driving and long day's work at first. Horses should not be troubled with sore shoulders at all if proper care is taken and well-fitting collars and hames are used, and that each horse always works in his own harness. Collars should last seven or eight years without being restuffed. They should be well attended to, and often tapped from the outer edge with a round stick or bottle. All harness should be well cleaned at least three times a year. Collars should always be turned lining upwards to dry at dinner time on dry days. I strongly believe in always watering a horse before it is fed. The horse with harness on cannot feed in comfort. The foal should be weaned at 5 or 6 months old and well fed, particularly until 1 year old. I have a great objection to horses being tied up at night ; they should have their freedom, so that they can lie down or roll if they wish. They should have a warm stable with a fair-sized yard in front, and a good stack of straw to rub against and help to keep them warm. Give as much good feed as they can eat when working hard, and feed two hours before going to work in the morning ; at other times give enough to keep them in good condition. Horses are often taken to the township, and to sports, and various other places and tied up all day, and often until early morning without feed, which is a cruel shame. Too much care cannot be taken with the horses' hoofs. If these were rasped and kept in proper shape two or three times a year there would be little need for shoeing the ordinary farm horse. A young horse often grows a long hoof, and it is often the best hoof, but through being left too long a piece often breaks out ; this weakens the other, and it also breaks, and often into the quick, which makes the horse sore-footed. We see many unsightly hoofs with large pieces broken out, for the want of little attention. Rock salt should always be kept in the feeder."

Mallala, August 4.

(Average annual rainfall, 16·88in.)

Present.—Messrs. J. Curnow (chair), A. V. Nairn, J. Nairn, S. Temby, F. and W. Konzag, W. McCabe, J. J. McCabe, E. Penfold, T. H. Warden, A. E. Temby (Hon. Sec.), and two visitors.

Feeding and Care of Horses.—The Hon. Secretary read a paper, from which the following is taken :—" Horses should have three good feeds of chaff daily and one of long hay at nights. Have regular hours for feeding, and do not give them enough at a time to last for several meals. Green wheaten hay makes the best chaff. Change the variety of feed occasionally, but always avoid giving musty hay or chaff. Old or low conditioned horses should have bran with their chaff, and be fed by themselves. It is not necessary to give the others bran unless they are doing heavy work for long hours. Mares in foal can be worked up to within a few days of foaling without harm. Then they should be put into an enclosure, with plenty of feed and water, by themselves. As a rule, foals are weaned when they are six months old. Lock them right away from the mares, and give them plenty of bran and chaff, and greenfeed occasionally, if obtainable. After they are weaned, allow them to come into the stable with the other horses. They are then quieter to handle. I think young stock are better if left until they are 2½ years to 3 years old before being broken in. Then only give them light work for half-days to start with. All working horses should be groomed at least once a day. Always pay special attention to their shoulders, and treat any sores immediately. For sore shoulders, some recommend powdered black lead mixed with clean melted lard. I have always found that a little turpentine mixed with vaseline answers very well. I prefer a well ventilated stone and iron stable with a good sized yard attached. With the iron roof there is not the risk of fire, nor the harbor for birds, as with the straw roof. Have the yard made of sawn timber, four rails, and 5ft. 6in. high. Divide the stable into stalls large enough for two horses to feed at, say, about 10ft. wide, using sawn timber. It is always advisable to have a fairly large loose box at one end. Avoid using wire around the stable yard. Do not tie horses up to the manger at nights, as they do not get the necessary rest. Leave the gate open after feeding at night, so that they can exercise themselves. Have the water-trough in the yard. This not only saves the time and trouble of taking them to drink, but the horses are more contented if they can have a drink when they please. Care must be taken to keep the trough clean. The stable and yard should also be cleaned regularly." Mr. J. Nairn preferred an iron-roofed stable, but would not divide it into stalls. He always kept a straw stack handy to the stable yard. The best policy to adopt when weaning foals was to allow them to have one drink from the mare daily for a while. Mr. A. V. Nairn would break in the colts at 2 years. It was a better practice when weaning foals to put them in an open paddock with plenty of greenfeed. Mr. J. McCabe would not feed horses on long hay unless it consisted of a fine-strawed variety of wheat. He allowed foals to have one drink per day when weaning them, otherwise it was necessary to milk the mare for the first three days. He would break young horses at the age of 2 years, if they were in good condition. Mr. W. McCabe preferred leaving them until 2½ years old.

Nantawarra, August 14.

Average annual rainfall, 15·90in.)

PRESENT.—Messrs. T. Dixon (chair), R. D. Nicholls, S. Sleep. W. Smith, W. Greenshields, R. P. Uppill, and G. S. Tucker (Hon. Sec.).

FRICTION.—In a paper on this subject, Mr. Smith said friction was reduced by the application of oil between the bearing surfaces, which prevented the metals coming into contact. Implements with quickly revolving parts, such as chaffcutters, engines, harvesters, and binders, without self-aligning bearings, should have the spindles set in proper alignment. Cheap lubricating oils played havoc with bearings, and increased the draught. Kerosine occasionally applied in the place of the oil would clean out any accumulation of old oil and dust. Grease was better than oil for plough and cultivator wheels fitted with oil cups on the outside. *Sore Shoulders.*—The best treatment in connection with this trouble was to tack a lining of tanned sheepskin to the inside of a well-fitting collar, and keep this well saturated with a mixture of oil and liquid carbolic. The former kept the collar soft and the latter was an antiseptic. *Master and Laborer.*—A great deal of friction between the farmer and his man could be got over if it were remembered that both were subject to human weaknesses. The careless employé and the nagging employer were not the rule, but they nevertheless existed. Mr. Sleep had found it impossible to work some horses without their getting sore shoulders. He did not believe in ill-treating animals, but if some horses were only worked when their shoulders were not sore it would not pay to keep them. In regard to friction between master and man, there was absolutely no need for it if the oil of commonsense were applied. The man that would stand a nagging master was not worth keeping. Mr. R. D. Nicholls believed that the extent of friction was in the ratio of 4 to 1, *i.e.*, well-oiled machinery which could be worked with one horse would require four horses if unoiled. He advocated the use of plenty of oil, but there was room for improvement in regard to its application, as there was too much wasted. It was a common sight to see oil over parts where there was absolutely no friction. A good deal of the friction between master and man could be avoided by a give-and-take policy. There were many things, small in themselves, which counted for much, such as a day off now and again, &c., which would help materially in creating a better understanding between employer and employé. Mr. Dixon had a horse that was very subject to sore shoulders. He tried new collars, the hollowing out of old collars, &c., but without effect. He found, however, that the best way to work the animal was in a steel collar around which bag had been wrapped. He believed in hollowing out collars in case of sore shoulders. Mr. Smith, in reply, said waste occurred through using oil which was too thin. He used common cylinder oil mixed with carbolic for sore shoulders for his horses, and found it effective. The trouble was due, to a certain extent, to infection and uncleanli-

---

Salisbury, August 5.

(Average annual rainfall, 18·57in.)

PRESENT.—Messrs. Moss, McNicol, E. V. Harvey, Tate, Frost, McGlashan, James, Shepherdson, Neal, Judd, Bagster, Whittlesea, Short, Urlwin, Fleet, Jenkins, and two visitors.

QUESTIONS.—In reply to questions handed in, Mr. E. Tate said that artichokes were of little value as feed to cows or sheep. Field peas were better planted so that they were just covered by the soil, but not deeper than ½in. Sowing about July was advisable, as the early sown crops were generally rank. About 2bush. of peas and 80lbs. or 90lbs. of super. should be used to the acre. Mr. F. Frost thought six cows would pay better than 50 breeding ewes in this locality, if it were not necessary to employ labor. If hand fed, he said, 200 sheep could be kept in the place of six cows. For lucerne in this district spring sowing of Hunter River variety was recommended. The best sort of wheat for hay was Baroota Wonder, but King's Early and Le Huguenot were the best for feed.

Two Wells, July 12.

(Average annual rainfall, 16·36in.)

PRESENT.—Messrs. P. C. Cooper, J. J. Rowe, J. J. Secomb, R. Kenner, H. M. Kenner, E. H. Green, H. Goss, W. S. Corden, and L. H. Dawkins (Hon. Sec.).

FALLOWING.—In a paper on this subject, Mr. H. Goss said heavy black soil could be advantageously ploughed in February or March when it was dry, to a depth of 5in. or 6in. It would work much lighter than if ploughed at the end of August or September. The fallow should be harrowed down not later than August and cultivated in September, and again in October or November, to just sufficient depth to destroy weeds. Light scrub land should not be ploughed when drying, and not more than 3in. or 4in. should be cut and turned over. Heavy clay land should be ploughed when just wet enough to allow of the plough working properly, the depth of working being regulated by the depth of soil. It should be harrowed in August and September, care being taken not to go on it when it was too wet, or the surface would be found to run together. Sandy land should not be ploughed too early, on account of its liability to drift. The plough could be best put in about the end of August or the beginning of September, the cultivator following just before the hay harvest; the soil being left rough, which would to a certain extent discourage drifting. In discussing the subject, Mr. H. W. Kenner said clay land should be ploughed early and harrowed as soon as possible afterwards, and sandy land should be ploughed late. Mr. R. Kenner advised the exercise of case to prevent clay being brought to the top. Mr. Cooper did not advise deep ploughing. He favored fallowing scrub land with the cultivator.

Watervale, August 11.

(Average annual rainfall, 27·17in.)

PRESENT.—Messrs. E. E. Sobels (chair), J. Pope, G. Hunter, R. Weymiss, N. Grace, T. Burgess, A. Burgess, W. Smith, H. Baker, D. Guthrie. O. Dunstan, A. Davis, J. Ward, sen., F. Hamp, J. Hamp (Hon. Sec.), and one visitor.

POTATOES.—Mr. Guthrie, in speaking of the suitability of this district for intense culture, said the land was capable of producing more than it was yielding at the present time. He believed the time was not far distant when families would obtain a living from about five acres. He intended going in for potato-growing, and asked for information as to the best varieties to plant and also regarding the cultivation of the land. Mr. Hunter recommended Pinkeye and Up-to-date as the most suitable sorts for this district. He would plough the ground deep and work it well and plant the sets 9in. apart, with 2ft. between the rows. If the seed were large he would cut them to one or two eyes on each set. Members agreed that potato-growing in this district would not be a very profitable undertaking unless the crops were irrigated.

PEAS.—Mr. Pope said it would pay owners of small blocks to sow peas, even if they were to take the place of bare fallow. The ground would greatly benefit on account of the addition of nitrogen to the soil. The best way to harvest the crop was to turn either pigs or sheep on to them when ripe. Mr. Burgess believed that peas, as well as many other such fodders, could be grown profitably.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Bute, August 12.

(Average annual rainfall, 15·42in.)

PRESENT.—Messrs. J. H. Barnes (chair), W. H. Sharman, M. Stevens, W. Buchanan, A. Schroeter, R. C. Commons, B. Lamshed, W. T. Matthews, E. W. Bettes, J. Trainor, W. Gardner, and L. E. Simon (Acting Sec.).

BULK HANDLING OF WHEAT.—Mr. S. Trengove introduced a discussion on the bulk handling of wheat. He was of the opinion that it was bound to come as the expense to farmers for cornsacks was now about 50 per cent. more than it was some years ago and there was no doubt there would be a further increase of 50 per cent. before long. There was too much rubbish shipped, and the freight on this was the same as on clean wheat. Mr. J. H. Barnes said that the paper which was read and discussed at the Whyte-Yarcowie Branch showed the cost of cornsacks, but did not state what would be the cost of the elevator system. No reference was made to the expenditure which would be incurred in altering conveyances, construction of trucks, and facilities at shipping ports which would have to be borne by the taxpayer. Mr. E. W. Bettes urged that the elevator system should be given a trial. Mr. L. E. Simon opposed the introduction of the bulk handling of wheat. If it were introduced at ports such as Port Adelaide, Wallaroo, Pirie, and Port Augusta, there would still be a large number of ports from which wheat in bags would, of necessity, have to be shipped. The farmers who marketed their wheat at these ports would have to contribute, through taxation, to the cost of erecting elevators at the ports mentioned. Mr. W. Buchanan referred to the fact that in Canada facilities were provided for the bulk handling of wheat, but he was of the opinion that the time was not ripe for its introduction in South Australia.

TWELVE YEARS AS HON. SECRETARY.—Eulogistic reference was made to the fine work in the interests of the Branch which had been done by Mr. L. McCormack, who was resigning from the office of Secretary and Treasurer, which he had held for 12 years, on account of leaving the district.

Kadina, July 10.

(Average annual rainfall, 15·88in.)

PRESENT.—Messrs. J. Malcolm (chair), R. Correll, J. N. Pedler, G. Bruce, B. N. Rodda, A. Paterson, and one visitor.

SHEEP ON THE FARM.—Mr. R. Correll contributed a paper on this subject. The farmer should, he said, discard the pure Merino in favor of the Lincoln-Merino cross or the English-Leicester cross. Continuing, the paper read:—"If a demand for these cross-bred ewes grows up as it should do, there are many people favorably situated for breeding them. The farmers should buy them as two tooths, and they could easily get four crops of lambs from them, and after that they could get more for the aged cross-bred ewe than they would for an aged Merino ewe, which would compensate for the extra price originally paid. The great advantage, however, is that the lambs will probably average 4s. or 5s. a head more. In addition there will probably be 20 per cent. more lambs, as there is always a loss with the Shrop. put to the pure Merino. The cross-bred ewes bring their lambs on better as they do not grow such a heavy fleece, and are much better mothers. The flesh is of a better color. This is the class of sheep that Professor Lowrie has been advising the farmers to go in for for a long time, and his address at the Saddleworth Conference, reported in the May *Journal*, is worth studying. It is true that this is a bad season to talk of lamb-raising to the farmers, but it is fair to assume that we are not likely to get similar conditions again for a number of years, so we may anticipate that fair average seasons are in front of us, and make our arrangements to keep sheep accordingly. There is one thing that we should not lose sight of, and that is that our export trade is likely to be good, and will improve if farmers put a good even article on the market." In conclusion, the writer urged the erection of a co-operative dip, and suggested that an effort should be made to secure special facilities for trucking lambs and sheep direct to the freezing works at Port Adelaide. In discussing the subject Mr. Paterson thought it inadvisable to trust to crossbreds alone. He recommended a cross with the Merino. Mr. Pedler thought it better to confine attention to one breed. He had averaged 10s. a head for lambs, and 9d. per pound for wool. Messrs. Bruce, Rodda, and Gordon also spoke, and urged all farmers to keep sheep and to cut straw from the stubbles to stack for winter feeding.

Minlaton, July 17.

(Average annual rainfall, 17·41in.)

PRESENT.—Messrs. J. Martin (chair), E. Correll, S. Vanstone, J. Boundy, D. M. S. Davies, J. W. Griffiths, A. Washington, R. H. McKenzie, A. D. McKenzie, A. D. Southerland, T. Giles, R. H. Tillbrook, J. McKenzie (Hon. Sec.), and one visitor.

DRY BIBLE.—Mr. Martin reported that one of his heifers appeared to have been attacked with this trouble. He gave her three packets of Epsom salts in the form of a drench, and several scalded bran mashes. The animal showed every sign of recovery.

Annual Report.—The Hon. Secretary read the annual report of the work of the Branch. This showed that 12 meetings had been held, in addition to one homestead meeting and a lecture by the Poultry Expert.

Minlaton, August 21.

(Average annual rainfall, 17·42in.)

Present.—Messrs. J. W. Griffiths (chair), J. Martin, J. A. O'Brien, H. A. Chester, C. Parsons, E. Correll, D. McKenzie, A. Washington, R. O. Page, R. H. McKenzie, A. D. Southerland, A. D. McKenzie, and J. McKenzie (Hon. Sec.).

Peas.—Mr. Parsons, who had had considerable experience in growing peas, did not think it advisable to feed them off. He had sown this crop on sandhills to prevent drift, and the results were good. Peas made excellent fodder, and could be preserved as ensilage.

Paskeville, July 21.

(Average annual rainfall, 16·10in.)

Present.—Messrs. J. P. Pontifex (chair), J. S. Bussenschutt, S. R. Price, J. Rundle, F. H. Bussenschutt, W. Rodda, E. W. Bussenschutt, T. E. Eylward, P. A. Uren, A. Goodall, G. H. Bammann, and one visitor.

Manuring.—Mr. Bammann contributed the following paper:—"Manuring the soil becomes necessary only when land has been to some degree exhausted of its available plant food. According to Jebro Fall, the originator of drilling and horse-hoeing, tillage might take the place of manure. By thorough tillage he grew wheat year after year on the same ground without manuring. He held that the decay of straw and stable manure in the soil was useful only in causing such a separation in the particles of earth as to reduce them to the condition of plant food—that is, to the soluble condition. He denied the actual manurial value of stable manure, and attributed its beneficial effect to its preventive and communicative action to the soil. In his day, farmyard scrapings was the only manure in constant use, and his view was, no doubt, partly correct. The mechanical effect of decaying vegetable and animal matter in dividing and pulverising the soil is fully allowed, as is also the carbonic acid evolved during decay upon the mineral matter of the soil." Mr. Goodall considered it quite possible, that by intense tillage, heavy dressings of farmyard manure, thereby providing a sufficiency of humus in the soil, and a very generous rainfall, profitable returns might be secured for a number of years successively, but still he would be inclined to question the wisdom of such a procedure in this district. Mr. Pontifex thought good results could be obtained by intense tillage and the ploughing in of vegetable matter and stubble, providing the ground was suitable.

WESTERN DISTRICT.

Elbow Hill, July 19.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. W. T. Cooper (chair), F. Freeth, E. Wake, J. F. Brooks, L. Wheeler, A. Ramsey, G. F. Wake (Hon. Sec.), and two visitors.

Wheaten Straw.—A paper was read, in which the writer advocated the erection of small straw stacks on different parts of the farm. These would be readily eaten by horses in cold weather or times of drought. Chaffed, and mixed with pollard, the straw made a good feed for working horses during the off season. Its value as a shed covering, also, could not be overlooked. Members generally agreed that the straw was of value as stock feed. The Chairman thought it necessary to add bran when feeding. If bound, the straw would be gathered free from dirt.

Goode, July 25.

(Average annual rainfall, 12in. to 13in.)

PRESENT.—Messrs. W. Folland (chair), C. Will, J. Rohrlach, Gene, W. Morcombe, W. Tainsh, H. Will, N. Packer, C. Lutz, Hughes, W. Burner (Hon. Sec.), and eight visitors.

HOMESTEAD MEETING.—Members took the opportunity of visiting the farm of Mr. N. Packer, and inspected the crops.

TANK-BUILDING.—Mr. W. Folland read a paper on this subject. The first essential in connection with the conservation of water on the West Coast, he said, was the selection of a site, on which a good run was assured, for a tank. One with a capacity of from 20,000galls. to 30,000galls. was quite large enough, as there was always a danger of it bursting, on account of the weakness of the ground. Fairly steep sides would be found to stand the strain better. For building, he advised mixing rubble, sand, and lime in the proportion of three, one, and one in the bottom of the tank, allowing it to stand for a couple of days to toughen, and then adding more water. A rough coating of from 4½in. to 5in. in thickness should be thrown on to the walls with a shovel, working right round the tank in tiers. The floor should be put in when the walls were finished. In the course of a day or so cracks would probably appear; these should be well filled. The walls and floor should then be plastered with a mixture of three parts sand and one of lime to a depth of 1in. to 1½in., leaving a good surface. Three parts of sand and one of cement should then be mixed dry on a piece of galvanized iron. This should be put into a kerosine tin with one side cut out, have water added, and be well stirred. It could then be applied to the wall with a hair broom, beginning at the top. By this means a good coat of cement would form at the weaker parts of the tank, *i.e.*, at the bottom of the walls. When this had dried tar should be applied, and then tar and pitch. Care should be taken to prevent the water getting behind the concrete, and good inlets and outlets should be provided. The roof, which would minimise evaporation, could advantageously be put on before the cementing was done, thus protecting the drying cement from too much action on the part of the sun. Mr. C. Will thought the cement should consist of two parts cement to five of sand, as the sand was not of good quality. Mr. Burner said amateur builders would do better by building round tanks. Mr. Whitelaw (a visitor) thought iron roofs cheaper than boughs in the long run, and there was the disadvantage with the boughs that they provided a breeding ground for red worms.

Goode, August.

(Average annual rainfall, 12in. to 13in.)

PRESENT.—Messrs. W. Folland (chair), H. L. Will, L. B. Hughes, W. Tainsh, N. Packer, J. Whitelaw, V. J. Tonkin, H. Packer, J. G. Rohrlach, W. Morcombe, W. Burner (Hon. Sec.), and two visitors.

HOMESTEAD MEETING.—Members visited the homestead of Mr. J. G. Rohrlach. The crops were found to be healthy, but backward. Particular interest was centred in a large flock of fowls, well kept, and nice looking pigs.

SHED ACCOMMODATION.—Mr. Tonkin thought straw sheds best for horses, as they were cool in summer and warm in winter; iron sheds were preferable for implements. Mr. Tainsh preferred iron for both, on account of the water catchment provided. Mr. J. Whitelaw preferred iron sheds, open to the east, with the chaff shed on the opposite side to the mangers. Members generally agreed.

Koppio, August 14.

(Average annual rainfall, 22·40in.)

PRESENT.—Messrs. W. R. Richardson, (chair), R. F. Richardson, T. Brennand, J. Newell, G. Howard, J. Liddy, G. Miller, sen., T. R. Gardner (Hon. Sec.), and three visitors.

SHEEP ON THE FARM.—Mr. J. Newell read a paper, in which he said the value of sheep on the farm was not generally realised. They were of considerable use in keeping the land clean, as well as providing the meat supply. It was not wise to purchase old sheep; those between two-tooth and full-mouth were best. Overstocking should be guarded against. Short, thick-woolled Merino ewes, of large frame, crossed with Romney Marsh rams were best for this district. He has been very successful with this cross, the loss at lambing being very slight. The progeny were not only good mutton sheep, but produced a good saleable class of wool. They were excellent mothers, and when crossed with the Merino ram yielded an ideal farmer's sheep, large-framed, hardy, and carrying an excellent fleece. Tailing should be done when the lambs were about two months old. One good sharp knife should be provided for the tail and another for the purse. Fire-branding, as well as ear-marking, was advised. Separate yards should be provided for catching the lambs and placing them in after treatment. These could be made of 3ft. 6in. pig netting, with posts 6ft. apart, and four wires. Mr. R. F. Richardson thought medium-woolled ewes would be better than the Merino. Members agreed that sheep should be kept on all farms.

Mangalo, July 19.

(Average annual rainfall, 14in. to 15in.)

Present.—Messrs. A. G. Burton (chair), W. E. Waters, S. Burton, J. C. Busch, H. S. and H. C. Mackley, H. C. McMartin, C. H. Klingberg, J. H. Cleave (Hon. Sec.), and three visitors.

Care of Farm Implements.—In a paper on this subject the Hon. Secretary said it was a mistake to erect a shed with mallee forks, brush, straw, &c., for covering machinery, on account of the danger of fire. An iron enclosure required no more timber for uprights and rafters, and was more quickly built, and there was the additional advantage of the water catchment provided. The machinery and implements of the average farmer to-day would need accommodation about 60ft. x 24ft. Native timber could be used for uprights and cross pieces, but 3in. x 2in. sawn hardwood was best for battens. The cost of the roof, including nails, guttering, and fascia boards, would be between £22 and £25. Drill boxes, wheels, wagon and dray bodies, if left in the rain and sun, would crack and split. Sand and dust filled these cracks, and further swelling under the influence of rain resulted in a great strain on joints, naves, or spokes, as the case might be. After the first year's work the implements should be overhauled, cleaned, and then dressed with boiled linseed oil, applied with a stiff paintbrush on all cracks, &c. Surplus oil should be carefully wiped off. After a week the whole surface of the machines should be gone over with the oil, a soft brush being used, which would effectively prevent the ingress of water. There would be no swelling or shrinking of the timber, and they would present a well-cared for appearance. A coat of oil every second year subsequently was then necessary. Breakages should be promptly attended to. Members generally agreed with the remarks of the paper writer, and deprecated the tendency of farmers to procure too many implements on the hire system.

Mangalo, August 16.

(Average annual rainfall, 14in. to 15in.)

Present.—Messrs. W. E. Waters (chair), S. Burton, J. W. Deer, H. E. Stienkie, W. J. Deer, H. C. McMartin, A. Schiller, H. C. Mackley, J. C. Bersch, J. Mieglick, J. H. Cleave (Hon. Sec.), and two visitors.

Rabbit Destruction.—Mr. S. Burton read a paper, in which he urged the erection boundary fences with posts 12ft. to 15ft. apart, with the barbed wire on the top, and one plain wire just below. Netting should be attached to the latter, and at least 6in. of this should be buried. This fence needed inspection weekly. Digging out burrows, and the use of ferrets were the best means of destroying the pest. The ferrets should be well fed and muzzled before being put into the burrows. Fumigating and poisoning were also effective. The poison cart could be advantageously used after the first rains of the season, before the grass grew to any extent. Mr. J. W. Deer favored the use of the poison cart. Mr. J. C. Busch recommended the regular use of the poison cart, together with fumigating and filling the burrows. Mr. McMartin had used a drum of bisulphide of carbon on a 100-acre paddock, in which there were a large number of burrows, with very good results. The majority of members agreed that the poison cart was the most effective method of destroying the rabbits.

Petina, June 28.

(Average annual rainfall, 13·19in.)

Present.—Messrs. W. Penna (chair), W. H. Howard, H. Doley, F. Goodhart, J. Souter, W. Schultz, O. J. Howard (Hon. Sec.), and one visitor.

Seeding.—Mr. H. Doley read a paper, from which the following is taken :—" Where one has a large area to put under crop, the sooner it can be got ready for the drill the better. The man who gets his ground ready, and then as soon as there is sufficient rain, pushes on with the drilling, will be best off in the long run. If the summer has been a dry one there is little fear of the grain malting if sown early, but when there has been much summer rain it is wise to wait. Most of the land in this district can be ploughed at any time, but it pays to wait for rain, to allow the grass to grow, and then to work the ground back. The implement I strongly recommend is a spring-tooth cultivator, but the land must be free from rubbish, and where one has rubbish to contend with a disc harrow is good, but the work needs to be done twice. By running the outside disc into the gutter each time the ground is double turned, and it becomes level. I am a great believer in deep ploughing, preferring nothing less than 4in. or 5in. If it is worked up well in the first instance a crop can be put on the stubble the next year. I have had some good results from drilling in on the stubble land that has been free from grass. If the season is favorable almost all the grain germinates, and thin sowing is advisable. I have had the best results with sowing at the rate of one bag of wheat and one of manure to every four acres. In some years, however, it proves to be a little on the thin side, as very often the ground is not right for quick germination, and the consequence is that a lot of the seed is lost. For hay, I recommend thick sowing, say, a bushel to the acre, as straw is wanted; but for stripping I find that with thick sowing the ears are inclined to be small. I am a great believer in grading the seed, or even running it twice through the winnower. By this means a lot of the small and inferior grains are taken out. In this district one needs to thoroughly pickle the seed, and as the country seems to be well suited for the development of smut, I prefer the McCabe pickler. I use ½lb. bluestone to the bag, but with wheat less subject to the disease I use less. Seed wheat requires changing from one locality to another, as almost any new wheat in a district does remarkably well for a year or two, and then it seems to deteriorate. The wheats I find most suitable for this district are the early varieties, and I prefer Steinweidel and Gluyas; Federation also does well, but is comparatively new to the district. Gluyas is best also for hay, as it is very heavy with plenty of grain, the horses like it, and it is generally ready for the binder early. It needs to be cut on the green side, as if left too long it becomes tough." A good discussion followed. Canon Howard suggested that the irregular spacing of grain in the drill rows was attributable to the grain being buried at varying depths, owing to the unevenness of the surface of the soil. Members thought the condition of the drill, or the sowing of damp or dirty seed caused the irregularity. Mr. Penna thought it would be an advantage to have the discs on the drill closer together, thereby distributing the seed more evenly over the surface. Members agreed that in this district it paid to fallow early, as deep as the type of soil would allow, and then to work the fallow. A good deal of trouble was caused by buck bush on the fallow. The best way to keep the land clear was good working. Mr. Goodhart said sheep would keep a large area clean, providing they were put on when the weeds were young. The Secretary spoke of the great damage done to the crops by the crows, and asked for a remedy. He had found poisoned wheat no use. Members had tried dipping pieces of meat in rabbit poison, but without success. Mr. Goodhart said the best way to keep them away from his wheat was to hang dead crows to sticks about the paddock. The common magpie was reported to be pulling up the young wheat, and also eating the grain from wheat heaps and open bags at harvest time. Jays were also doing a great amount of damage to the young crops. Mr. Schultz desired to know whether fallow would yield a more payable crop than land that had been ploughed after harvest, both being saturated with moisture at seeding time, and both receiving the same amount of seed and manure at the same time. Members favored fallow, because the action of the sun and air during the summer months would set free a large quantity of plant food and also sweeten the soil. The practice of burning stubble before ploughing came in for a good discussion. Members thought that unless land was being fallowed it was best to burn the stubble. The stubble left the land too open for a good seed bed. Instances were pointed out where this had been so. It was usually, though not always, best to burn before drilling stubble land. Canon Howard suggested that members should experiment with the idea of determining the value of harrowing growing crops.

Petina, July 19.

(Average annual rainfall, 13·19in.)

Present.—Messrs. W. Penna (chair), D. T. Kenny, W. Schultz, J. Bascombe, J. Souter, E. Keeley, J. H. Wharff, O. J. Howard (Hon. Sec.), and six visitors.

Breeding and Breaking Horses.—Mr. W. L. Schultz read a paper, in which he recommended farmers to breed good strong horses that could be readily sold. He thought the majority of mares in this district were on the small side, therefore it was advisable to select a good sized draught stallion for service. It was better to pay £5 for the use of a good sire than £1 or 30s. for the service of a mongrel. When castrating colts, it was advisable to avoid windy or frosty days. The animals should be roped as quietly as possible, and on no account should they be run round and made to sweat before the operation was performed. The ropes round the legs should not be tied too tightly, and the beasts should be kept down for as short a time as possible. He preferred the use of the searing iron and resin to the emasculator. The best time for castration was about August or September, when the animals were yearlings. Foals castrated at the age of 1 month seemed to get over the operation more quickly than those castrated at the age of 1 year. When breaking, it was advisable to secure the animal in a strong yard. A strong rope, with a slip-knot, should be run round its neck, the operator taking two turns around a strong post with the rope, and drawing the colt up. If it threw itself down, the person holding the rope should allow it to slacken gradually. A strong pair of winkers should then be put on, the bit being put into the mouth after the throat lash had been done up, and the animal then run round for a while, first in one direction, and then in the opposite. Following this, a collar and harness chains and a spider should be put on, a good steady horse being placed in front of the colt, a strong neck-rope on the latter being tied to the spreader on the chains of the former. One man should lead the horse, and one should be on each rope attached to the ring of the bit on the colt. After they had been run round for a while they should be attached to a small log, and after walking around with this for some time, the colt should be put straight into the wagon with a good team. Half a day's work without too great a load was sufficient for a start. After the collar was removed the shoulders should be washed with cold water. Members did not agree with the writer in that the big upstanding horse was the most suitable for this district. Mr. Wharff, some years ago, went in for large horses, but found them a failure. The small short-legged, large-bodied type of horse did as much work (because it was quicker), did not require as much feed, and was a much better doer in the paddock. The Hon. Secretary said the so-termed mongrel was the best horse for this district, providing he was well built. The Chairman drew attention to Mr. Kenny's horses. They were small, but drew heavy loads and kept in good condition although working hard. They were a very staunch lot. Mr. Kenny attributed this to the fact that they were all broken in to the buggy. Members did not agree that September was the correct month for castrating colts. Mr. Kenny and Mr. Penna, both of whom had had considerable experience, said that February and March constituted the best period. The colts were not so full-blooded and were not so likely to feel the effects; they would be about 18 months old at that time. Hot weather was the best in which to do the operation. They favored the emasculator, although Mr. Penna often used the knife alone.

Roberts and Verran, August 12.

Present.—Messrs. R. Johnson (chair), F. Masters, W. H. Whittaker, D. Hoar, C. Reiman, E. K. Phillips, H. Ede, J. A. Buttfield, W. Kunst, C. Kunst, A. T. Cowly, F. Imhoff, H. Sharman, and W. Sharman (Hon. Sec.).

Destroying Shoots.—Mr. W. Sharman read a paper, in which he advised early rolling of mallee, to allow the shoots to become well advanced before the time for burning arrived. A warm day, with a suitable wind, should be selected, and it would be found that a good burn would result in a better stubble for burning the following year. The sowing of oats was a good idea, as these carried the fire well. Land ploughed the first year generally produced fewer shoots than that disked. It was usually in the second year that the shoots were troublesome. If a running fire could not be secured the use of the fire rake should be resorted to. If knocked down the straw would be more destructive to the shoots when burning. The harrows could be used for this purpose, or in the absence of these the fire rake itself. A fire should go over all land, irrespective of whether it was to be cropped or not. For fallowing, the use of the disc implement was best. The sooner shoots were cut after seeding the better. Mr. Cowly had tried the grasscutter for cutting shoots, but there was trouble with loose sticks, &c., and it was necessary to go over the ground twice. Messrs. W. Sharman and W. H. Whittaker had tried fire-raking on fallow, but the ground, being loose, smothered the fire. Mr. J. McCallum favored the harrows for knocking down the straw. Mr. Phillips preferred the fire rake. The single-tooth implement was best. Members thought that if the fire rake were built higher it would carry a greater body of fire, which would be an advantage.

Shannon, August 9.

PRESENT.—Messrs. Proctor (chair), Wilkins, Inglis, C. and W. Wemyss, J. Carey, Fitzgerald, H. Roediger, and J. J. Cronin (Hon. Sec.).

FALLOWING.—The following paper was read by Mr. S. A. Wilkin :—" Fallow is essential where wheat-growing is to be made a success, for it is admitted by all successful farmers that the fallowed land gives better results than green or newly-ploughed land. It is also a great help in the way of getting the seeding over early, as it is possible to treat a much greater area with a cultivator than if the land had to be ploughed. Fallowing allows the rain, frost, and sun to penetrate the soil, which sweetens it. Ploughing to a depth of 3in. to 4in. will suit this district. The plough should not cut more than 7in. furrows, and all the draught possible should be kept on, to move the roots. All fallowing should be completed by the end of August or middle of September. It should then be harrowed and cultivated on the cross with a disc cultivator. This implement will cut a good number of the shoots, besides bringing the land to a fine tilth. One hundred acres put in crop this way would be worth 200 acres of stubble land. Grass land should be fallowed as soon as seeding is over and while the ground is wet, because these paddocks generally become firmly trampled down by the stock. Cut the holding into three parts ; for example, a farm of 900 acres should have 300 acres in crop, 300 acres under fallow, and 300 out for grazing. Sheep should always be run on the land which is intended for fallowing, as they keep down any weeds and manure the land to a certain extent. In some districts summer or autumn fallowing is a considerable advantage, but I do not think it would do for this district, as the land is too hard, and the stumps are too firm. The wetter the land the better. Late fallowing has a tendency to encourage takeall. Early fallowing and early working will starve out this disease, which is a very important point. It is a good plan to sow a little rape or turnips on the fallow where the crops have been affected with takeall. This will help to check the disease, besides providing a little summer feed for sheep." Mr. Carey would not fallow the land if the practice could possibly be avoided. If the stubble were fire-raked the shoots could be kept under for a year. Mr. Inglis would summer fallow. The Chairman thought there was more risk of takeall if the stubble were fallowed than if the land were left out for a year.

Utera Plains, July 19.

(Average annual rainfall, 12·06in.)

PRESENT.—Messrs. J. Abrook (chair), A. Venning, W. Gale, M. Abrook, W. Stephens, H. Rule, G. Barber, W. Lee, G. Hornhardt, H. Warnes, and A. Ramsey (Hon. Sec.).

SCIENCE AND THE FARM.—Mr. H. Rule contributed a paper, in which he drew attention to the dependence of the farmer on the work of the scientist. The present high standard of knowledge in matters relating to agriculture, he thought, was the result of careful scientific investigation, and the work of the scientist was complemented by the practical applications of his discoveries on the part of the farmer.

Utera Plains, August 16.

(Average annual rainfall, 12·06in.)

PRESENT.—Messrs. N. Guidera (chair), J. and M. Abrook, A. Venning, G. and H. Barber, W. Gale, J. Norton, G. Hornhardt, A. Ramsey (Hon. Sec.).

FEED AND WATER.—Mr. J. Abrook read a paper, as follows :—" The most pressing problem for farmers at the present time is feed and water for stock. If we get through the present drought it behoves everyone to see to it that at least two years' supply is stored up during good seasons to take us safely through dry times like the present. I do not suggest any combined action, but that every landholder should act for himself. Let us take ourselves to task and consider whether, if instead of passing 10 out of 30 years foraging for water, we had invested £100 in iron and timber, and constructed sheds and tanks, we should not be in a better way to-day. As far as one with a permanent supply is concerned, of course, the storage of water does not apply, but if the immense quantities of cocky chaff and straw that are annually burnt were stored up in a large shed one could always make it come into use in bad years. If not required by the owner it could be disposed of with advantage, and the shed would provide a catchment for water for household purposes, of which there is usually a shortage. If the harvester were fitted with an arrangement suitable for handling chaff I think it would be an advantage. One could keep it cleaner and better for using than if put through a stripper and threshing machine, that process giving too many backbones. The water supply is overtaken by the growing demand, whatever steps are taken. No surface catchment could give a sure supply of water at all times with a 12in. or 14in. annual rainfall. In the eastern end of this district the run would be only very occasional, the greater part of the fall putting nothing into the tanks or dams. Capital expended in galvanized iron catchments would be a much more economical investment than carting water at cost of about £1 per 1,000galls., which is, I think, a fair estimate of the cost. I would strongly advise anyone going on the land to make provision for an adequate water supply—not to muddle along anyhow." In discussing the paper, members said that where the amount of capital was limited, they would place iron on the ground to provide a catchment for water; otherwise, however, sheds, which could afterwards be used for the storage of implements, etc., should be erected.

Yabmana, August 9.

(Average annual rainfall, 15·14in.)

Present.—Messrs. M. K. Frost, G. G. Pengelley, J. F., G. G., and A. Robertson, W. Schirmier, J. H. and C. E. Frost, F. A. and A. Beinke, J. M. McCallum, H. P. McCallum (Hon. Sec.), and six visitors.

Care of Farm Horses.—Mr. J. H. Frost read a paper, as follows:—"Stabling is undoubtedly of first importance, for without a warm, comfortable stable a good percentage of the feed given to horses is practically wasted. When building a stable on the farm it is not necessary to incur a lot of expense. Timber suitable for the purpose can usually be procured without much trouble. Pine or gum will be found to stand for a number of years, provided a little care is exercised in its selection. A straw roof and iron or stone walls will be better than an iron roof; the former being cooler in summer and warmer in winter. The stable should open to the east. Feeding is of next importance, and should receive more attention and forethought than is generally given it. Regularity is everything; it should be the aim of every driver to feed his team at the same hour every day. Always water the horses before feeding, as they will then clean up their feed better. Avoid giving hay that is at all damaged or musty, as this is the cause of a good deal of the trouble with horses' health. When the drinking water is perfectly fresh it is well to place a few lumps of salt in the manger. On farms where a lot of horses are kept it is, perhaps, not practicable to groom them every morning, but it will be found labor well spent to clean them as often as possible. Always brush the shoulders before putting on the collar, as dry sweat is liable to cause a scald. When a horse gets a sore it should be well washed after the day's work, and some embrocation should be rubbed in. A bad fitting collar is more often than not the cause of sore shoulders." In the discussion which followed, members generally agreed with the views set forth in the paper. Mr. J. F. Robertson would water the team after feeding if they did not get a drink in the middle of the day. If the collars fitted the horses properly, and were stuffed and lined, when they became flat and hard there would be no trouble with sore shoulders. Mr. F. A. Beinke thought horses required three drinks a day, and would give these before meals. A straw stable was better than an iron one. The Chairman said watering horses was a matter of use; if they were watered before feeding they would always look for it.

Yadnarie, July 16.

(Average annual rainfall, 14·09in.)

Present.—Messrs. F. W. Dreckow (chair), W. L. Brown, G. A. Dreckow, J. A. Krüger, A. Spriggs, A. A. Jericho, R. H. Parbs, F. H. Stubing, J. J. Deer, F. G. Fitzgerald, A. Priess, S. H. Pearce, C. Dreckow, R. B. Deer (Hon. Sec.), and five visitors.

Fallowing.—In a paper on this subject, Mr. A. Priess said that as soon as the farmer had determined which paddocks he intended fallowing, he should put stock on these to keep the feed down. The fallowing should commence immediately after seeding, and the depth of the working should be regulated by the nature of the soil; loose limy soils requiring much shallower ploughing than hard clayey land. The light skim plough was the most suitable for shallow working. The harrows should be put over the land across the ploughing to encourage the germination of the seeds. The cultivation should not be done too early in the spring, or it might be found necessary to do the working twice, as the weeds would possibly grow again. These could well be kept down by sheep, which animals would also assist in solidifying the subsoil. With new land, however, especially in this district, less cultivation was required. If it were ploughed and left until the following autumn before cultivation, the sun would have a better opportunity for sweetening it, especially in the case of tussocky land. It was a good idea to skim over in the autumn land intended for fallowing, which would have the effect of burying weed seeds, possibly resulting in a good growth with the early rains. Members generally agreed with the ideas of the writer of the paper.

Yadnarie, August 15.

(Average annual rainfall, 14·09in.)

PRESENT.—Messrs. F. W. Dreckow (chair), W. L. Brown, J. A. Kruger, E. C. Kruger, A. Spriggs, A. A. Jericho, R. H. Parbs, L. H. Marston, F. H. Stubing, G. B. Kobelt, J. J. Deer, S. H. Pearce, C. Dreckow, and R. B. Deer (Hon. Sec.).

HARNESS.—Mr. J. A. Kruger read a paper on this subject. Harness, he said, was more generally knocked out than worn out. It should be thoroughly overhauled two or three times a year. Brown harness was more durable than black, on account of the fact that the latter was treated with a chemical dye, which removed much of the natural grease. The best process of cleaning was to take the harness to pieces and wash it well with warm water and soft soap. The inside faces should then be dressed with a thin coating of neatsfoot oil, whilst some harness dressing should be applied to the outside. Surplus oil should be carefully removed. Collars should be kept in the shade. Check lining was cheaper and cooler than leather, which was likely to scald the horse's shoulders. In the event of the appearance of sores on the shoulders the collar should be hammered with a bottle and eased. The draught of the hames, or the uneven length of the chains might be responsible. The paper was discussed at length.

Yallunda, August 23.

(Average annual rainfall, 18in. to 19in.)

PRESENT.—Messrs. F. Olsten (chair), R. B. Jenkins, G. Provis, T. V. Provis, W. Cabot, H. P. Cabot, T. Forrest, W. Forrest, M. Hissey, T. Allen, S. L. Dix, J. S. Perry, G. Gill, A. Price (Hon. Sec.), and two visitors.

AGRICULTURAL BUREAU.—Mr. H. P. Cabot read a paper, in which he urged on members the necessity for enthusiasm in connection with the Branch, and pointed out the benefits, both educational and social, which accrued from the meetings. They had the opportunity of securing advice from the experts of the Department of Agriculture. Whilst some persons had the idea that because they did not feel competent to contribute a paper or an address their attendance at meetings was not desirable, he pointed out that the interchange of ideas resulting from discussion on different matters of agricultural interest was of considerable value, and in this all could take part.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Bandon, August 1.

PRESENT.—Messrs. J. D. Lee (chair), W. Johns, W. Spurling, J. T. Retallack, G. G. White, R. Copp, P. Purdie, J. T. Corbett, H. Cope, jun., W. H. Spurling, M. J. Walsh, C. A. Evans, A. Dohse, L. Dohnt, W. Johns.

THE AGRICULTURAL BUREAU.—Mr. G. G. White contributed a paper, in which he urged on members the necessity for realising the responsibility involved in membership of this organisation. The object of the gatherings was the dissemination of knowledge on matters of agricultural importance, which would result in raising the standard of farming and enable them to avoid mistakes which had been made through inexperience in the past. Loyal support to the officers of the Branch was most important, and strong personal interest would ensure the success of the Branch.

Borrika, July 19.

Present.—Messrs. E. H. Huxtable (chair), R. Collins, N. Collins, L. G. Huxtable, J. Woods, J. L. Sandercock, A. E. Seary, J. H. Gray, G. Back, V. V. Brown, R. J. Stephens, J. E. Coombe, H. S. Green, H. Richards, C. W. B. Traeger (Hon. Sec.), and one visitor.

Colic.—Mr. E. H. Huxtable read a paper, in which he said that farmers should exercise considerable care when changing horses from grass to dry feed. There was a danger of colic, which trouble took two distinct forms, viz., spasmodic and flatulent. The former, if not promptly relieved, would in severe cases result in inflammation of the bowels, and the latter would show marked enlargement of the stomach, due to the generation of gas, which, if not checked, would probably have a fatal result. The general symptoms were—the animal became suddenly seized with pains in the bowels, restless, uneasy, adopted a crouching attitude, and, at times, struck at the stomach with a hind foot and gazed at the flank, exhibiting signs of great distress. After several efforts, generally it would be found to get down and roll about, sometimes on its back and frequently right over. The pain appeared to pass off quickly, and the animal again began feeding, but after an interval the symptoms returned with increased violence. The best treatment was to comfortably rug the beast and immediately administer the following drench:—Two ounces peppermint, 2ozs. sulphuric ether, 1oz. laudanum, and 1 pint of soft water. This should be thoroughly shaken and kept corked prior to administration If the animal were not relieved the drench should be repeated in about 45 minutes' time. In back country places, where drugs were not readily obtainable, it was advisable for the farmer to keep a small chest of medicine on hand, or, as a preventive, secure a few drenches from a reliable veterinary surgeon.

Borrika, August 16.

Present.—Messrs. E. H. Huxtable (chair), J. Waters, jun., J. Waters, sen., L. G, Huxtable, J. Woods, J. L. Sandercock, W. Mayfield, A. E. Seary, A. E. Hart, G. Stephens, V. V. Brown, J. B. Tonkin, R. J. Stephens, H. J. Stephens, H. S. Green, P. J. Marker. C. H. A. Tonkin, S. R. Haynes, F. Edwards, C. W. B. Traeger (Hon. Sec.), and two visitors.

Harvesting Machinery.—Mr. Gray read a paper, in which he said—"From the little experience I have had with harvesters in the North, I am of opinion that they are very little heavier to draw when the wheat-box is full than when empty. The reason is that the harvester carries the load on the near side of the main wheel, which is high and wide, and the load is also direct behind the horses. Being built on the off side of the main wheel there is a considerable amount of side-draught. This could be done away with by having the machinery built on the near side of the main wheel. The whole load would then be directly behind the team. This would mean a complete revision of the whole machinery. Taking all things into consideration, the stripper has advantages over the harvester in these parts. Harvesters draw heavily in sandy soil and over stumps. Wide strippers and a power winnower would suit the mallee farmers' requirements in harvesting his crop in the long run. It is better to do the threshing and cleaning at the heap than drag a small winnower around the paddock all day long. The farmer would then be able to save his cocky chaff for his stock in case of a dry season, such as we are experiencing at present. There is less tear and wear of machinery with this method. Purchasing a power winnower, of course, means a considerable outlay the first year, but this difficulty could be overcome by two or three settlers getting one machine between them. As these machines involve labor by this co-operation, this requirement could be obtained. In the case of power winnowers, with the engine on the same stand as the winnower, there is a certain amount of vibration; but on the other hand, when a portable engine is used, it means extra work when shifting, on account of change of wind or from heap to heap. There is an idea that a horse-power winnower has a detrimental effect on the legs and feet of horses which work in the treader. We have not found it so. By changing horses every hour and feeding them well they will put on condition during the cleaning. The motor power has advantages over the horse-power winnower. There is more power to deal with rough heady stuff, and the horses can be put to other work. The engine can also be used for chaffing hay and crushing corn. When a hand winnower is used it may be advisable to use damp weather strippers. The draught of these is greater than that of the ordinary strippers. A machine which works the thrasher with a direct drive, that is, by a separate belt from the main flywheel, will be lighter in draught than a thrasher which is driven by means of an intermediate pulley. With a direct drive the belts grip the pulleys well, and the machine can be driven with a comparatively slack belt. In regard to ordinary strippers, one requires durability and lightness of draught. To obtain this the machine needs to be built of light but strong material, and possess high and wide wheels; a long platform, or front carriage, so that the machine will run straight; medium size beaters, and an adjustable comb. There should be just sufficient comb over the off-wheel to clear the wheel. When the comb is set some distance out from the off-wheel there is a danger of catching the off-corner of the comb in stumps when stripping a low crop. Large beaters are heavier to drive, and a smaller beater is inclined to spit or spill wheat over the comb, so I would recommend a medium size. A machine with a 6ft. comb is a handy size. Larger or wider machines can be worked, but that means additional side-draught. The side-draught can be lessened by riveting aprons—curved strips of tin—to the roof of the machine, which will guide wheat to the near side. It is advisable to use a binder with a 6ft. cut, as it will work just as well as one with a 5ft. cut. The working depends largely on the driver."

Clanfield, August 16.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. A. Richards (chair), W. Paull, A. Correll, A. Orwell, L. Orwell, H. Pavy, E. A. Pavy, C. Paul, W. J. Booth, G. Watson. P. Nelson, J. Nelson, A. G. Franklin, and H. Milne (Hon. Sec.).

Manurial Tests.—Most members were in favor of experimental manuring being undertaken by the department in this district, to be a guide to farmers who cannot afford to spend much on experimental work. Instead of only working on cleared land, it was thought a start should be made on newly-burnt land, and tests carried out that would be a help to the producers in this and similar country.

Claypan Bore, August 12.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. J. Gray, S. Gray, E. Colwill, Horace Colwill, Harold Colwill, C. Hill, W. Webb, F. S. Tall, and five visitors.

Mixed Farming.—Mr. E. Colwill read a paper on mixed farming. Although this district was not yet thoroughly adapted to the keeping of large numbers of sheep, he said it would pay every farmer to keep from 50 to 100, both for household purposes and to keep the fallow free from weeds without too much working of the same. One sheep should return on the average £1 per year by producing the lamb, the fleece, and the mutton. *Cattle.*—This was not dairying country, but a few good cows for milk and butter supplies, with a surplus of butter for market, should be kept. For this purpose he recommended the Hereford-Shorthorn cross. The Shorthorn would give the milking qualities and the Hereford the beef. It was best to kill the calves and rear pigs with the separated milk. *Pigs.*—Pigs did well on warm separated milk. Only good breeding sows should be selected, and he favored the pure Berkshire breed. The progeny of these fattened and grew rapidly, the meat being of the finest quality. If the farmer desired to go in for a cross, he recommended the white Yorkshire sow, as this breed generally carried a large litter. They should be mated when 12 months old, and he considered it paid best to sell pigs just after weaning them. *Poultry.*—For poultry, clean and well protected houses and yards were necessary, because the birds must be protected from foxes. Although White Leghorns were the best layers, for farm purposes he would cross these with Black Spanish cockerels. Chicks should be raised as early as possible in the spring, so that they might be sufficiently advanced to withstand the heat of the summer, and start laying in the autumn. He preferred to rear turkeys and geese for table purposes rather than to breed heavy fowls. There was always an increasing demand for eggs. In the discussion which followed, the Chairman considered it a mistake to kill calves and rear pigs instead. A few weeks' feed and attention given a calf was all that was necessary. Without further trouble or expense a beast could be raised which at 2 years would be worth £5 or £6. Mr. J. Gray advised rearing high-class stock, and the constant endeavor to improve the quality of the herd. The Hon. Secretary preferred to purchase yearlings as stores, rather than to rear the calves. He recommended the Ayrshire-Jersey cross, as a fine-looking animal, capable of yielding large quantities of milk. Members all favored the pure Berkshire as the best all-round pig for the farm; but the Secretary said, if going in for a cross he preferred the Tamworth-Berkshire to any other. If the farmer provided a good straw bed for the pigs they did not require as much feed as if left to rough it. Wheat fed to pigs should be boiled or crushed. The Chairman preferred crushing to boiling. Mr. J. Gray did not recommend mating White Leghorns with Black Spanish, as suggested by Mr. E. Colwill, as both varieties were weak. He had found this district admirably adapted to the rearing of poultry, owing to the total absence of lice and tick, which he attributed to the presence of sand. The home of lice and tick was in the cracks in the woodwork of the roosts, but owing to the poultry carrying a certain amount of sand on their feet up on to the perch these cracks became filled with sand. Chicks hatched in August and September throve better than those brought out in October and November. Laying hens should not be allowed to fatten, as if so, a decrease in the number of eggs would soon follow. The fowls should be given plenty of work and be made to scratch amongst a heap of cocky chaff or straw for their corn. When using an incubator, great care should be taken to put same in a place where there was as little variation in temperature as possible. An ordinary "dug out" would be suitable. A good cross breed for the export trade was the Silver Wyandotte and the Silver Grey Dorking. Turkeys were good sitters, having been known to sit as long as three months and hatching three and even four sittings of eggs in this time.

Shoots.—To destroy shoots, the Chairman recommended cropping for three consecutive years and burning the stubble. With good burns each year the shoots at the end of this time would practically all be destroyed. To obtain early feed he advised running a disc cultivator over stubble previous to fallowing. This would cover most of the wheat wasted by the stripper, and given an early rain there would soon be ample greenfeed for grazing purposes. He emphasized the necessity of making provision for the feeding of stock in the event of a dry season. Oats mixed with cocky chaff would tide the stock over until the rains came. It would pay during a dry period to feed sheep at their present market value on hay worth £3 per ton in the stack.

Takeall.—Mr. L. McCormack (visitor) said dry fallowing of land of a loose flowing nature, after the second crop in new country, was the main source of takeall. The air would have too free access to the root of the plant in land of this class, and death would ensue. By fallowing land early and when in a wet condition there was practically no danger of the fungus ravaging the crop.

Coomandook August 16.

(Average annual rainfall, 18·01in.)

Present.—Messrs. Ninnis (chair), A. Bald, P. C. Potter, C. Mitchell, N. Brown, L. Crouch, H. Gosden, F. Byerlee, A. Bung, M. Wilkin, R. Williams, E. Luxmore, R. Byerlee, O. Blucher, L. Williams, and C. M. Wilkin (Hon. Sec.).

Question Box.—The meeting took the nature of a question evening, and a number of subjects of interest were dealt with. It was thought that three successive crops were sufficient to kill mallee shoots. After this the land should be fallowed or grazed. Applications of super. were advised as follows:—The first year, after a good burn, 56lbs.; second year, 70lbs.; and third year, 80lbs. to 90lbs. The skim working of a large acreage in this district was thought more profitable than close attention to a smaller area. The best varieties of wheat were Federation, Gluyas, Yandilla King, and Darts Imperial. Members thought the principle of the mallee shoot scorcher, which had been tried in the district, good, but improvement was necessary, as a machine on four set wheels would not turn satisfactorily in stumpy and sandy country. the wheels were in the case under notice set too low; four horses for a machine with a 6ft. cut were too many; and the sprocket chain was too light. A dobin was thought an unsuitable vehicle for general carting on the farm.

Coonalpyn, August 15.

(Average annual rainfall, 17·49in.)

Present.—Messrs. Gurner (chair), H. Bone, J. Hill, G. H. Wall, E. E. Williams, R. F. Venning, J. J. Cronin, A. H. Fidge, D. T. Cronin, F. J. Tregenza, G. E. Venning (Hon. Sec.), and six visitors.

Harvester *versus* Stripper.—Mr. J. J. Cronin read a paper on this subject. He thought the stripper more suitable for this district, on account of its lighter draught, the saving of the cocky chaff, and because there was less grain lost. He very much doubted whether the harvester would yield a good sample of wheat without the loss of a good deal of grain, when it was being worked on undulating country, especially if there were any wind. The cost of the stripper was much less than that of the harvester, and its life was much longer. However, there was a saving of labor with the latter machine at harvesting time, and under favorable conditions it might be made to last long enough to compensate for the extra cost. However, wheat left in the bags at harvest time was just as much liable to damage by thunderstorms as that in the heap. The reaper thresher was a slight improvement on the harvester, but it was too cumbersome and expensive to be useful to the majority of farmers. Mr. Wall favored the harvester on account of the saving of labor which it effected. Mr. Bone mentioned that mallee shoots caused trouble in the sample of grain when the harvester was used.

Lameroo, August 16.

(Average annual rainfall, 16·55in.)

Present.—Messrs. E. J. Trowbridge (chair), O'Connor, Leckie, J. H. and J. F. Jericho, J. Cameron, F. W. Eime, Ross, Mead, S. G. Trowbridge, A. J. A. Koch (Hon. Sec.), and one visitor.

Co-Operative Dairying.—The following paper was read by Mr. O'Connor:—"A creamery is of the greatest advantage in any community where a sufficient number of cows is kept within convenient distance for gathering the cream. The butter is generally of better quality, being made under the best conditions by one person who is an expert, and the quality is uniform, which is a most important factor, in so far as the marketing of the produce is concerned. The system of co-operative dairy-farming is not a new one by any means, and has been successfully carried on in various parts of the world, particularly in Denmark and Switzerland. It owes its origin to private enterprise, and the system is simplicity itself. The farmers in a district unite together, and form amongst themselves a society, with a view to sending their milk to one common establishment, there to be made into butter and cheese, the proceeds of which are divided amongst the members in proportion to the quantity of milk each has contributed. Under the conditions that exist throughout the greater part of the Pinnaroo district is seems feasible that a co-operative butter factory could be successfully carried on. At present, perhaps, the majority of farmers, on account of the vast amount of labor entailed in the clearing of their land, have little time to devote to dairying, but considering the special advantages this district seems to offer in many respects, I trust it will not be long before earnest consideration is given this question. In the first place there is abundance of water, and with a highly retentive subsoil and an average rainfall of somewhere about 16½in., there should be little to worry about concerning pasturage. We know from experience that the class of feed that grows in these districts is highly nutritious, and apart from the natural food that exists it has been proved by numerous experiments that various classes of fodder can be successfully grown. The farmer who depends upon wheat-growing alone is often the slave and victim of the adversities of season, weather, and markets, and it is inimical to his success to make use of his land for other purposes, apart from the entire cultivation and raising of crops for grain. The dairying industry is one that has made rapid strides during the last two decades, in fact, more so, perhaps, than any other branch of agricultural pursuits. Even in the north of South Australia, where wheat-growing has comparatively proved a failure, it is the dairying industry that has enabled the people to remain on their properties, and the regular proceeds from the sale of cream has been their chief means of providing for their requirements. I should think that the greatest and most effective development of the dairying industry in any district peculiarly suited for it would be through a co-operative system of disposing of the products. Under efficient management a co-operative creamery should prove a success. I have not, however, had an opportunity of going into figures, and merely make the statement with the view of inviting discussion and getting the opinion of some present who are thoroughly practical; but I know from experience in business that the farmers who had only a few cows seldom had large accounts to pay, and frequently had balances to their credit. Under co-operation every farmer who supplied cream would become a participator in the profits of the concern, and in such a large district as this it should not be long before the output of cream reaches large dimensions. In some parts of America, where co-operative creameries obtain a certain price for cream is fixed for the season, in accordance with the price of butter, and leaving a small fund in hand which is divided at the end of the season, or the price of cream is raised or lowered, according to market fluctuations. The creamery system is of general application, and may be made available both for the co-operative dairies and for large single dairies. Its greatest and most effective development, however, is through co-operation, by which a large number of farmers and small dairymen may enjoy its benefits. Generally, the dangers of co-operation with large business concerns are a lack of individuality and initiative. There is not the same incentive to economy and efficiency as is natural to the operations of a person who is working directly in his own interests, but in a comparatively small concern as a co-operative creamery in the Pinnaroo district, where the members would be almost in daily touch with the management, and frequent discussions as to necessary reforms or alteration in business methods could be held conveniently, there is not the same difficulty in this respect. In any co-operative concern it behoves the members to be loyal to the undertaking which they have helped to establish. Farmers in particular are a section of the community who should be able to co-operate with success. Their interests are identical, and anything they can do to improve the lot of their neighbor reflects also upon the whole population, as a generally successful comunity of farmers means better land values and better prices for commodities. The present system of Agricultural Bureaus is a true form of co-operation, farmers being prepared to expound for the benefit of their fellows the various results obtained from various styles of working." Mr. Kumnich thought this district, with its abundant water supply, well suited for this industry, and in years to come hoped to see farms split up and much dairying carried on. Practical experience had shown that where farmers had become members of these co-operative creameries they had invariably done well. Mr. F. W. Eime said natural grasses here did not produce much butter, but self-sown wheat and oats fed with a little chaff night and morning gave excellent results. If co-operation were started, all would need to feed alike. Regularity was most essential. The dairyman was courting disaster by missing a milking. It would pay farmers to always keep a good class of cow and cull out wasters. His cows were at present each making from 12lbs. to 14lbs. of butter per week. Mr. Townsend (visitor) said that years ago individual dairying was carried on in and around Mount Pleasant and Onkaparinga, and no headway was made. A co-operative butter factory was started; special feeding was adopted, and as a result, men who were once struggling were now well off. The Chairman was inclined to think that good milkers could be obtained from any breed if they were carefully selected. He believed in co-operation if it were worked on careful and economic lines.

Loxton South, August 14.

(Average annual rainfall, 12in. to 13in.)

Present.—Messrs. W. B. Russell (chair), A. J. Lowe, B. F. Beer, J. H. Beer, C. T. Durdin, C. Swinburne, E. Stokes, and A. J. Durdin (Hon. Sec.).

Clearing Mallee.—Mr. Russell stated that if mallee were cut between the months of April and August the shoots would get a good start before the scrub was burnt in February. The fire would kill these, and shoot-cutting would be obviated for the first year. This had been supported by experience on his own farm. Some members said that when they secured two good stubble burns hardly any green stumps were left to shoot.

Fencing.—It was pointed out that the hollow white mallee stood well for fencing posts, but red mallee succumbed to the attacks of white ants. Pine was generally favored for posts. They should be cut before the sap rose, and allowed to dry before being put into the ground.

Monarto South, August 16.

(Average annual rainfall, 14in. to 15in.)

Present.—Messrs. G. Patterson (chair), A. P. Braendler, R. E. Anders, J. Frahn, G. Gogol, A. and R. Hartmann, B. Hoff, A. Patterson, J. G. H., R., and G. Paech, A. Schenscher, B. and C. Thiele, E. Tilbrook, H. Zeunert, C. F. Altmann (Hon. Sec.), and six visitors.

Takeall.—Mr. A. Hartmann read a paper, in which he said, "In my opinion and experience takeall is a disease affecting various soils more or less. It is prevalent on light sandy soils, and worse on limestone and rubbly soils, but heavy stiff and clay soils are not so subject to it. I do not think it is a disease of the wheat plant itself, as it affects the plant more during wet seasons, with mild and cold temperatures during its growth, and seems to be disappearing in dry seasons. But I have noticed patches of takeall in dry seasons. There are several different stages during the growth of wheat when it may be attacked. I have seen a whole paddock affected three or four weeks after germination. The color of the plant shows a tinge of yellow, instead of being green, and the crop gradually dies off towards the maturing stage and in the warmer weather.

Sometimes when the wheat is about 12in. or 18in. high, patches from 3ft. to 30ft. in diameter of a yellow color will appear. These gradually extend week by week, until there is hardly anything left. The disease may not appear until after the flowering stage. Where patches of whiteheads appear, extending as the ripening process goes on, one will notice a good deal of pinched grain under the winnower. Some of the heads attain their normal size, but the grain either remains undeveloped or very much shrivelled. The straw and ears of such diseased plants present a bleached appearance. The plant proves to be dead, and the base of the straw and roots show a blackened appearance. Takeall will also affect oats, barley, and grass, but not to such an extent as wheat. All the varieties of wheat are more or less subject to the disease, but especially Federation. One will find insects resembling flies, but half the size, in large numbers, when the crop is ripe, wherever takeall appeared during winter and early spring. They are very troublesome to the horses and driver when stripping. Therefore, I conclude that the soil is diseased and is not in a fit state to grow crops when takeall is prevalent." Some members were of the opinion that oats were immune to takeall. A desire was expressed that other Branches should report as to whether small grey flies were to be found in numbers on patches affected with takeall.

Monteith, August 22.

(Average annual rainfall, 14in. to 15in.)

PRESENT.—Messrs. D. J. Travers, J. F. Connell, A. Clark, J. Ferries, T. S. Bradford, R. Magor, J. Rowan, sen., W. H. Carter, T. Kelly, A. A. Wells, O. E. Male, W. G. Gunn (Hon. Sec.), and six visitors.

BREAKING LIGHT HORSES.—In initiating a discussion on this subject, the Chairman advised first lassooing the animal, then hobbling both its hind and one fore feet together. A rope could be attached to the free foot, and, if necessary, a turn taken around the body to hold it up. He would lead the colt on horseback for six or seven miles and ride it the second day, using a good saddle and bridle, girth, two surcingles, and monkey straps attached to D's deep in the saddle. The animal should not be encouraged to buck, but good strong tackling should be used. Mr. Scott preferred educating the colt in a yard about four panels square with the aid of a whip. After 20 minutes at this he would put on a saddle and bridle and ride the animal in the yard ; it was well for the operator to be quite alone. Mr. Carter preferred roping the beast. Kindness and patience were essential. Mr. Male did not think the use of monkey straps advisable. The Hon. Secretary had noticed the following method adopted by a breaker :—First the colt was run into a stable with a quiet reliable horse. Hobbles were placed on the front feet and the animal allowed to walk about in the yard. The operator then approached the animal with a light stick. The horse was then mounted and the hobbles were removed. For harness education the animal could be put in a light trolley with a good reliable horse, and run for a few miles daily for five or six days.

Morgan, August 16.

(Average annual rainfall, 9·29in)

PRESENT.—Messrs. R. Wohling (chair), J. Pope, E. Hausler, H. Wohling, O. Hausler, J. B. Hoffman.

QUESTIONS.—For the destruction of green grubs in gardens Mr. E. Hausler recommended the use of one tablespoonful of coal tar in a gallon of cold water. Members generally preferred crossbred pigs. Mr. E. Hausler recommended the Berkshire-Essex cross for curing, on account of the tender quality of the flesh.

Parilla Well, July 25.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. R. Philbio (chair), J. E. and J. W. Johnston, D. B. and J. S. Ferguson, E. H. and H. Leak, T. Burford, F. and H. Nordhaussen, F. C. and A. Webster, J. Flavel, W. Flavel, and L. G. Neville (Hon. Sec.).

ROTATION OF CROPS.—The Hon. Secretary, in a paper on this subject, said the practice of alternating wheat and fallow had many points in its favor. Fallowing became much more easy, as the land did not become so hard, there was an absence of the numerous small shrubs which throve on sandy soils if left undisturbed, and usually a good stubble burn could be secured. The use of the plough, also, would not be necessary. If the land were worked up in the autumn, directly after the stubble was burnt, a larger amount of moisture would be conserved. It was questionable whether the third year rotation of fallow, crop, and grass would give profitable results in this district for some years, as sufficient herbage to sustain stock had not yet made its appearance. The sowing of oats or barley for feed in the place of allowing the land to lie out in grass, would overcome this drawback. Mr. J. W. Johnston thought most farmers in the district had more land than they could handle under the alternate wheat and fallow system. With the third year rotation it would be found that better results were obtained if the area under oats were left out for two years. Mr. J. E. Johnston thought the cultivator unsuitable for fallowing, as it did not pull stumps. Mr. J. S. Ferguson thought crops of wheat after oats might be tried with advantage. The Chairman thought good fires essential. A system he had noticed was wheat, grazing, fallow, and, although there was a tendency for the weeds to die out, little trouble was experienced with takeall. The plough was best for fallowing, as it weakened the roots of stumps.

Sheep.—At a previous meeting, in discussing this subject, Mr. J. E. Johnston said the increased growth of weeds in the district would make it necessary for farmers to keep sheep. Mr. J. W. Johnston thought these animals profitable, even if it were necessary to yard them. Mr. A. Inkster recommended the Shropshire-Merino ewe crossed with the Romney Marsh ram for lamb-breeding in this district.

Rabbits.—Mr. J. W. Johnston found the ploughing in of burrows the best means of coping with rabbits. Netting was essential to keep them back from breakwinds and scrubs adjacent to the farms, but the netting was liable to become covered with drift. Mr. A. Inkster agreed that the use of netting was essential.

Renmark, July 28.

(Average annual rainfall, 10·93in.)

Present.—Messrs. W. H. Waters (chair), J. S. Higgins, H. de Witte, H. S. Pike, M. B. Geneste, G. Agars, H. S. Taylor, H. D. Howie, H. B. Williams, J. N. McDougall, W. F. Snow, F. Cole (Acting Hon. Sec.), and two visitors.

Pruning.—In retailing impressions gathered during a recent visit to Mildura, Mr. H. S. Taylor exhaustively explained the long system of pruning which had been adopted by Mr. Sage, of the Wentworth Irrigation Settlement. He thought the exceptionally heavy crops secured by that gentleman were attributable to the system, and the trees were showing no signs of distress.

Sutherlands, August 16.

(Average annual rainfall, 10·60in.)

Present.—Messrs. J. Badge (chair), J. H. Geyer, Dohnt, Snell, Mibus, G. Heusler, Twartz (Hon. Sec.), and three visitors.

Sore Shoulders.—Mr. Badge read a short paper on this subject. A simple remedy recommended by Mr. Badge was a mixture of clean fat, or better still, pig lard with blacklead and powdered wattle-bark. With this mixture applied healing would take place, even though the horse was being worked. It was a mistake to cut a hole in the collar, for this caused a lump in the shoulder, and if the horse were sold, or a fresh collar put on, a new sore would be made at the old spot.

Wilkawatt, August 16.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. D. F. Bowm n (chair), W. J. and D. Bowman, jun., J. W., F. W., E., and G. A. Altus, J. and A. V. Ivett, T. Sorrell, A. J. McAvaney, F. and B. Spackman, W. R. and M. Neville, H. H. Brooker, H. H. Pritchard, D. Horgan, B. Tylor, P. Gregurke, J. Wade, M. Hayes, W. J. Tylor (Hon. Sec.), and nine visitors.

Light Vehicles.—In a paper under this heading, Mr. D. Horgan said that when light vehicles were used in wet weather they should be washed and dried before being put away. If this were not done the wood work would swell, and dished wheels would be the result. A good coat of paint closed the grain of the wood, filled up cracks, and preserved the wood from the effects of the weather. Varnished wheels should be given one coat each of raw and boiled oil, and a good coat of varnish when they were thoroughly dry, every two years at least. The buggy was the most suitable vehicle for this district, as the four wheels stood the rough roads better than two wheels. Patent oil cap axles were advisable for sandy country. Hickory spokes were best; ironbark was not a suitable wood for this purpose.

SOUTH AND HILLS DISTRICT

Blackwood, August 11.

(Average annual rainfall, 27in. to 29in.)

Present.—Messrs. W. L. Summers (chair), E. and A. K. A. Ashby, Wilson, H. Sullivan, Sibley, A. W. Carlos, and A. A. Magarey, P. H. and D. Williams, Dall, Penno, Porter, Nicolle, Turner, Eglinton, Hunter, Winser, Hilfers, Davis, James, and Savage (Hon. Sec.).

Fertilisation of Fruit Tree Blossoms.—The following paper was read by the Chairman:—"It is hardly necessary for me to remind you that unless the blossoms on our fruit trees are fertilised we cannot have a crop of fruit, and, consequently, anything that lays within our power to assist the agencies which bring about this fertilisation, or to bring about conditions condusive to the same warrants our earnest attention. We know that it is necessary for the pollen to come into close contact with the pistil of the flower under suitable conditions to cause fertilisation, but it is remarkable how little we do know about the factors governing this act of nature. We know that some varieties are what is known as self-fertile, that is, their pollen is capable of fertilising their own flowers, while, on the other hand, some are self-sterile, that is, require the pollen of some other variety to bring about fertilisation. We are also told that the insects and the weather are important factors in this process, but what we lack is definite information concerning these points which we could put to practical use. How frequently do we find that trees blossom freely and yet set very little fruit; pears, citrus, and stone fruits might be quoted more particularly. Then do we not often get a better crop of fruit from what we might term a fair blossoming than from a heavy one? Then we have some varieties that we can depend upon to set the fruit if the blossom is there, and other kinds that we cannot. We often try to explain to ourselves why these things should be, and our views are often contradictory, for the simple reason that we are merely guessing at the causes. My object in dealing with this subject, which I admit I know little about, is to endeavor to awaken sufficient interest to induce growers to go to a little trouble during the coming season to note which varieties of trees blossom together, the weather conditions at blossoming time, whether insects, and especially bees, are busy amongst the flowers, whether any varieties set better than others in comparison to the amount of blossom, and if so, whether any local conditions exist which may account for this. If growers would take careful note of these points for a few years and publish the results through the Bureau meetings and the press, we would soon secure a great deal of local knowledge which would greatly assist in the object we all have in view, *i.e.*, the production of maximum crops. Not only does this question of the pollenation of the flowers directly affect the yields from our trees in the matter of numbers of fruit, but also in the matter of the size of the fruit. The Horticulturist of the Oregon Experimental Station, in reviewing the results of their work, states that it is interesting to note that the crossfertilised blossoms produced fruits containing more seeds than blossoms not crossfertilised, and, further, that the greater the number of seeds in individual fruits the larger the fruits. Fruits may mature and yet produce no seed, due apparently to imperfect fertilisation, but there is ample evidence that seed production in fruit is an exciting cause of growth. We have an instance of this in the Zante currant; the buck or seeded fruit is always much larger than the seedless or normal fruit. During the past few years I have been keeping notes of observations reported from various parts of the world in respect to this subject, and these notes form the basis for the views which follow. Reference to standard works on horticulture give one very little definite information, and suggest that the subject has not in former years received the attention it deserves. It is recognised that there may be many contributing causes to failure in the fertilisation of the blossoms. Of these the following are probably the most important:—*Weather Conditions.*—Unseasonable weather at the blossoming period, such as excessive heat or cold, heavy rains, hail, or frost have disastrous effects on the blossoms. Frosts and hail will also injure the fruit after fertilisation has taken place. Bearing on this phase of the subject the following summary of the results of observations made by Professor Sanderson, at the Wisconsin Agricultural Experimental Station, are very interesting :—' The vitality of pollen is not seriously affected by temperatures ranging from 25° to 55° C. in dry atmosphere. Temperatures under 25° seriously interfere with the germination. A temperature from 70° to 80° C. in a saturated atmosphere is fatal to the pollen of the peach, apple, and plum. At a temperature of 40° to 50° C., in a saturated atmosphere, the pollen burst open, due to the rapid inhibition of water, and the number of bursted pollen increased as the temperature increased. This bursting of pollen actually takes place in masses of apple and plum pollen during warm spring rains. Freezing temperatures ranging from 1·5° to 1° C. were not seriously injurious to the pollen of the apple, pear, and plum, while less than 50 per cent. of peach and apricot pollen were killed by this temperature. The pistils of the varieties named were more susceptible to the low temperature than pollen. Temperatures ranging from 1·5° to 0° C. kill the pistils. Sunshine has little or no effect on the germination of pollen, or upon the growth of the pollen tube in most plants. There was, however, a slight increase in the rate of growth in favor of sunshine. The germination and growth of the pollen of the tomato is decidedly retarded by cloudy weather, and also the anthers of the tomato require a certain amount of sunshine for the proper development of the pollen. The same is true in several species of lilium. The lack of culture and fertility in orchards greatly injures the production and fertility of pollen. The longevity of apple, pear, and plum pollen depends on the conditions in which it is kept. If kept in a dry place in a temperature ranging from 7° to 26° C., apple pollen can be kept for six months or longer, while few plum pollen germinated after being kept for six months. Pollen may safely be shipped from one part of the country to another without losing viability or fertility. Under favorable conditions it requires nine to 32 hours for the pollen tube of apples, plums, and cherries to reach the ovary when placed on the stigma or in the germinating medium. Cherry pollen requires a little over 12 hours. Under natural conditions the time required would be somewhat greater since the rate of growth is increased with the increased temperature up to the optimum degree which, in the case of apple, pear, and plum pollen, is 24° C. This would indicate that the length of time required for the germination is considerably less than is commonly believed. Two or three bright warm days at the time of full bloom is sufficient for the setting of fruit. The stigma of apple pollen are receptive from four to six days, whether pollinated or not. Continuous rainy weather for six days would probably result in total failure of the crop. The factors which affect the fertility and production of pollen, over which the orchardist has control, may be briefly stated as follows :—Suitable site, location of soil, pruning and spraying, proper planting, cultivation, sufficient amount of plant food, selection of suitable varieties propagated from bearing trees, and the planting of several varieties which flower at about the same time, to insure proper fertilisation. The factors over which the orchardist has little or no control are : freezing temperature, which may kill the pistil or the pollen, especially before the latter are ripe, or both ; continuous rain during full bloom of the orchard ; high temperature with a large amount of moisture and absence of wind, which causes much pollen to burst at the time of germination ; and absence of insects and wind at the time of full bloom. In endeavoring to trace the amount of injury due to unseasonable weather conditions, we must have some definite knowledge of the periods over which the different varieties bloom in the different districts, as well as of the weather conditions of the district, if we are to minimise loss from this cause. *The Vigor of the Tree.*—Pollination may fail, owing to the excessive vigor or excessive weakness of the tree. The farmer may be counteracted by taking such action as may be necessary to reduce the tree to normal growth ; the latter better cultivation, drainage, manuring, or irrigation, according to circumstances. Excessive blossoming also appears to have a disastrous effect, and, in some instances good results have been obtained, especially with pears, by thinning out the spurs, removing weak ones, and reducing the others where considered desirable. If we examine any branch on a healthy mature pear tree and count the spurs we will find that if each spur mature one pear it would be far more than the branch could carry. As, however, each spur will throw many blossoms the need for judicious thinning is apparent. *Insects and Diseases.*—Fungus diseases exercise a destructive influence on the blossoms, but, fortunately, the grower can materially lessen, if not prevent, loss from this cause. Pears in particular are subject to such injury, and it is recommended to spray with Bordeaux or Burgundy mixture when the buds are just coming out of the spur, but before the blossoms open. This will not only assist in the setting of the fruit, but will also prevent to a large extent injury to the newly set fruit which causes malformation. Some varieties, and the Glou Morceau may be mentioned, are particularly subject to this trouble, even in this district, where there is not as a rule much loss from fusicladium injury. In apricots we have a good deal of loss of blossoms from what is usually called 'black bud.' This appears to be due to the attack of shothole or other fungus late in the autumn, and autumn spraying is recommended wherever it is prevalent. Insects exercise both injurious and beneficial effects, according to the nature of the insects. Thrip and red spider are injurious, but preventive measures are at the disposal of the grower. Other insects which visit the flowers to gather pollen and honey do an important work for the grower, as they carry pollen from one flower to another on their bodies. It is, however, a much disputed point as to whether these insects actually cause the fertilisation of as large a proportion of the blooms as is frequently claimed. In a report issued by the Oregon Agricultural Experiment Station, the Horticultural Expert states that probably 99 per cent. of the fertilisation of the blossom is due to insects, and that bees are the most important of these. At the Oregon station the peach trees which were screened to prevent bees and other insects obtaining access to the flowers, set a fair quantity of fruit, but most of it fell at the stoning period, whereas those trees adjoining to which the bees had access matured abundant crops. At Kansas, the results of a similar test with a number of varieties of trees was the same. In Colorado, a leading horticultural writer states that the setting of fruit in that locality is in proportion as the bees are numerous or scarce. In California, repeated instances are given of orchards formerly yielding sparse crops giving good returns when a number of hives of bees have been brought into or adjoining them. In the United States Department of Agriculture Year Book, M. B. Waite emphasises the value of bees, and says 'Be sure there are sufficient bees in the neighborhood to visit all the blooms, and where possible encourage the bees to visit the orchard by planting in a warm sheltered spot, or by planting windbreaks.' On the other hand, a grower in New South Wales, speaking on this subject, stated that he believed that the value of bees had been greatly over-rated, as he always had plenty in his orchard (of Jonathan and Sturmer apples), but had a poor setting of fruit, except in the rows where the two varieties were in close proximity to each other. He points out that a bee will obtain all the pollen it will carry at one trip on visiting 80 to 100 flowers, so that the number of bees required to fertilise the blossoms in a large orchard would be enormous. Other authorities are also inclined to doubt whether bees play anything like such an important point as the wind in carrying the pollen from one blossom to another. If the bees are as important a factor as generally suggested it is easy to see that indirectly the weather plays a very important role as mild sunny days at the blooming season will render the bees, &c., active while gloomy cold weather will keep them in the hives. *Lack of Other Varieties of Trees.*—Here we have a most interesting phase of this question, and one that, if it is as important as most observers are inclined to believe, is quite within the control of the grower. It is well known that the planting of large blocks of one variety frequently results in disaster, and numerous instances could be quoted where success has followed the grafting over to some other variety flowering at the same time of a percentage of the trees. The grower should ascertain what varieties flower at the same period, and we can all help by keeping records. The records being kept in the Government orchard will be of great value in a few years, but they cannot be relied upon entirely as the relative periods of blossoming of different varieties vary in different situations. We also want to determine by actual records what varieties are self-fertile and what self-sterile, or partially so. Curiously enough, even this appears to vary in different districts. The Williams, or Duchess pear, as we know it, is regarded as more or less self-sterile in the Eastern States of America and in Australia, yet in California, under the name of Bartlett, it is quite self-fertile, and is planted in solid blocks of many acres in area. Then, again, Beurre Clairgeau, Gansels' Bergamot, L'Bonne de Jersey, Winter Nelis are more or less self-sterile in Eastern America, whereas Clairgeau and Louis Bonne de Jersey are considered self-fertile in other parts. The Howell is regarded as self-fertile in California and the reverse in Australia. We have these same differences with apples. It will be seen from the foregoing how important it is that we should know what varieties bloom about the same period, and I would strongly urge members to make note of this. What we want to know is (*a*) when the first blooms are out, (*b*) when the tree is practically in full bloom, and (*c*) when the bloom is off. With (*a*) and (*c*) this does not mean when the very first bloom is out or the last, but when there are a reasonable number of normal blossoms out. Before dealing with one of the most important aspects of this question, from the practical point of view, *i.e.*, interplanting varieties; I have some notes gathered from different sources in respect to apples and pears—time does not permit of going further—dealing only with the leading varieties. *Apples.*—Jonathan and Cleopatra flower with Newtown, Prince Alfred, Red Astrachan, Reinette du Canada, Strawberry Pippin, Williams' Favorite Rokewood, Yates' Statesman. The Yates is considered one of the best to fertilise the Jonathan, but its lateness in maturing is an objection which will be referred to later. Dunn's Seedling and Spitzenburg flower with Emporer Alexander, Garibaldi, Irish Peach, Bismarck, Ribston Pippin. London Pippin and Rome Beauty flower with Adams' Pearmain, Buncombe Delicious, Hoaves, Lord Wolseley, Nickajack, Northern Spry, Winter Magetin. *Pears.*—Records at Burnley, Victoria, showed that in 1910. 300 out of 347 varieties of pears were in bloom between September 27th and 29th, but this was abnormal, and was attributed to excessive warmth at that period, hastening the blossoming of the later varieties. The average period of blossoming was about 16 to 19 days, according to the season. The Keiffers, Gansels' Bergamot, and Winter Nelis appear most self-sterile, Williams' Bon Chretien coming next. In regard to flowering, Williams' Bon Chretien flowers at practically the same time as B. de Capiamont, Josephine de Malines, Duchess D'Anjou, Madame Cole, Glou Morceau. Kieffer blooms with Le Coute, Harrington's Victoria, Doyenne du Comice, Broom Park, Howell, Duchess de Angoulime. Gansels' Bergamot blooms with B. Diel, Glou Morceau, and Winter Nelis. Winter Nelis blooms with Gansels, B. Beurre Diel, Seckle, Vicar of Winkfield, and Easter Beurre. It must be understood that the above is only a partial list, that is the result of only two years' records, and being for one locality only will probably not apply in every district and in every season. *Interplanting of Varieties.*—All authorities are now agreed that unless a variety is known to be perfectly self-fertile in a particular district it is unwise to plant large blocks of trees of that variety. Even in such instances interplanting is considered advantageous, and three or four row blocks of one kind are considered best. In planting the different varieties it is advisable to have the rows run across the direction of the prevailing winds at the blossoming period. In deciding what varieties to plant together we must know which bloom at the same period, and other things being equal, select varieties that ripen fairly close together. Avoid planting an early and a late maturing variety in alternate rows for the reason that the traffic in harvesting the early variety will consolidate the surface soil with the probable result that the later kind will suffer from lack of moisture. Examples of undesirable extremes, where the question of moisture is of importance, are Jonathan and Yates in apples, Williams' Bon Chretien and Glou Morceau in pears."

Cherry Gardens, August 12.

(Average annual rainfall, 35·03in.)

Present.—Messrs. H. Jacobs (chair), J. Lewis, G. Hicks, T. Jacobs, sen., J. Tozer, S. W. Chapman, H. Lewis, A. Broadbent, T. Jacobs, jun., A. R. Stone (Hon. Sec.), and three visitors.

Rabbit Destruction.—An instructive paper under this head was read by Mr. T. Jacobs, jun. The writer contended that the rapid increase of the rodent in the district called for serious attention of landholders. Not only did they attack crops, but orchards, and especially young trees, were very frequently damaged. They were also of considerable trouble in the vegetable gardens, and vineyards also received their unwelcome attention. Especially were they destructive in the case of muscatelle vines, the leaves of which they ate before the fruit had matured, with the result that the crop failed to ripen. Another cause of annoyance had been the undermining of roads by the burrows. The writer was of the opinion that systematic and simultaneous action on the part of landholders would result in their eradication. Wire netting was a great advantage. The first step in the direction of destroying the pests was to keep them out of the ground by digging out or blocking up their burrows. Continuing, he said—"Fill each opening as tightly as possible with titree, bracken, or any shrub that is handy, and cover up with earth or stones. Some of these may be reopened, but care should be taken to prevent the rabbits taking possession again. Destroy any new burrows that may be commenced as soon as discovered. In rocky places it will be found most difficult to deal with the holes. In such cases it is best to block every hole possible, and set traps around the remainder. Where the rabbits are thick it is necessary to poison them. Commence this when the feed is dry and scarce. Care should be taken to use only the poison that is least dangerous to stock. After they have been reduced considerably by this means and grow too wary for baits, the remainder can be killed with dogs and guns. Some might say this is too expensive, but it is one of the quickest and most effective ways of destroying the pest, especially where they are only scattered. Besides, there are only three or four months in the year when the skins do not pay for the cartridges used, and it is evident that we cannot eradicate the pest without considerable expense, whatever means we use. Get rid of all thickets of every description that are likely to harbor the rabbits. It is surprising the number that two or three dogs kill in a year. Practically no young ones escape, and I venture to say it would only be but a matter of two or three years when we would have the satisfaction of having the district quite free of the pest." In discussing the subject, Mr. Hicks mentioned that he had had good results from placing pieces of newspapers in the mouths of the burrows. The rabbits seemed to dislike scratching on anything noisy. Mr. T. Jacobs, sen., thought scrub, titree, and ferns efficient for blocking burrows. Mr. J. Tozer said the closing of all holes for a period of 48 hours would destroy all rabbits inside. The holes were usually reopened from the outside. The exploding of dynamite in burrows situated in rocky places not only wrecked them, but filled the passages with poisonous fumes.

Clarendon, August 11.

(Average annual rainfall, 33·67in.)

Present.—Messrs. T. B. Brooks (chair), H. C. Harper, J. Spencer, C. C. Spencer, W. A. Morphett, L. Masters, J. Piggott, A. L. Morphett, A. Harper, A. A. Harper, J. Potter, J. R. Nicolle, E. Dunmill, L. Spencer, H. Rowley, A. Phelps (Hon. Sec.), and two visitors.

Fruit-Growing.—Mr. A. L. Morphett read a paper, in which he stated that within a radius of a few miles of Clarendon there were hundreds of acres of land suitable for fruitgrowing. Apples did extremely well in the valleys and on the hillsides. In Tasmania, as much as £30 per acre was paid for similar country, and the cost of clearing for planting in many instances involved another £30. The average annual income from an acre of apples, established in bearing, should equal £25, and 16 acres should provide a good living for a family. The difficulty was that for six years there would be no return, whilst for a further three years or so the returns would only repay the cost of upkeep, &c. The prospective orchardist should procure the most up-to-date labor-saving machinery and implements, and pay careful attention to the selection of the trees. Members generally

Forest Range, July 17.

(Average annual rainfall, 35in. to 36in.)

Present.—Messrs. W. McLaren (chair), C. Dolman, E. and F. Rowley, W. Tribe, A. and F. Green, E. Dearman, H. Sass, E. Green (Hon. Sec.), and two visitors.

Poultry in the Orchard.—Mr. W. Tribe read a paper on this subject. The continuous decrease in the numbers of native birds, chiefly insectivorous, he said, had allowed an appreciable increase in insect life. When poultry were kept in orchards they assisted in keeping these pests in check. The droppings of the birds were of considerable manurial value, and fruit which fell to the ground, and which would otherwise remain as a harbor for pests, would be readily eaten by the birds. Where they were likely to do damage to the smaller fruits or vegetables, either these could be enclosed with wire netting or the birds could be confined in movable pens. The sale of eggs and birds should return sufficient to at least recoup all expenses, after the requirements of the household had been supplied. At the prices ruling at present there should be a fair profit in keeping the fowls. The heavier breeds were preferable, for whilst the Leghorns were best for egg production they were difficult to confine. Mr. F. Rowley thought poultry profitable if they were well looked after. Silver Wyandottes were best for this district. Mr. F. Green thought this locality too cold for egg production. Mr. E. Rowley favored yards of from three to four acres in extent with portable houses. He preferred White Leghorns, a good strain being essential. Mr. E. Green thought fowls too great a nuisance in the orchard, and they did not diminish the insect pests to any appreciable extent.

Forest Range, August 14.

(Average annual rainfall, 35in. to 36in.)

Present.—Messrs. J. Green (chair), W. McLaren, J. Vickers, E. Rowley, A. and F. Green, R. Collins, C. Dolman, H. Schultz, H. Trevenen, E. J. Green (Hon. Sec.), and two visitors.

Pruning Apples.—Mr. A. Green thought it advisable to prune old apple trees the year prior to an anticipated good crop, or directly after a full crop. Mr. Schultz preferred to prune the trees regularly each year. Mr. J. Green pruned his trees lightly in an off season, but heavily when a full crop was expected, and satisfactory results had been secured. Mr. Vickers thought an off season the best time to prune an old tree, but heavy pruning of healthy trees in an off year resulted in the growth of large quantities of wood, but little fruit. Mr. F. Green preferred heavy pruning the year previous to large crops. Mr. J. Green had cinctured about one-sixth of a Nickajack apple tree; this portion carried a nice crop of fruit, but the untreated part bore practically none. Members agreed that deep planting of fruit trees was not advisable in this district.

Hartley, August 13.

(Average annual rainfall, 15in. to 16in.)

Present.—Messrs. B. Wundersitz (chair), S. Beavis, S. Pratt, C. Klenke, G. Hill, G. Phillips, W. Cross, D. Clark, B. Klaebsch, P. Wagenhaccht, A. Wundersitz, T. Phillips, W. Bermingham, J. M. Hudd, D. F. Westwood, J. T. Forbes, J. Hudd, F. Lehmann, J. Stanton (Hon. Sec.), and two visitors.

Working a Farm of 500 Acres.—Six members read papers on this subject.

Mr. F. Lehmann said that as about two-thirds of the district was good arable land, and the balance good grazing country, with a three years' rotation on an average farm of 500 acres about 110 acres could be cropped, 80 acres fallowed, and 310 acres grazed. Six horses should be sufficient for the work, and two of these could be of the roadster type. Two foals could be reared yearly. The stock could also include 10 milking cows, two sows, about 150 sheep, and 150 head of poultry. The income would approximate from 110 acres wheat and hay, £150 (after horse feed, hay, seed, and fowl and pig feed had been deducted); 150 sheep, lambs, and wool, £110; butter, £70; poultry, £70; pigs, £20; sale of cattle and horses reared, £40; a total of £460.

Mr. W. Bermingham recommended that the homestead should be placed on rising ground in the centre of the holding. About 150 acres should be fallowed as early after seeding as possible to a depth of 5in., if the soil were stiff, but to a less depth in lighter soils. A harrow could with advantage be attached to the plough. The ground should be cultivated to a fair depth during September, and harrowed or cultivated after summer rains. At seeding it should be again cultivated to a depth of 2in. Weeds should be fed-off with sheep. A light harrow could be attached to the drill. Plenty of hay should always be on hand. The harvester was better than the stripper. All the animals should be well fed.

Mr. J. M. Hudd advised dividing the area into three paddocks of 150 acres each, three of 5 acres, 20 acres being allowed for waste land, and 5 acres for the homestead. Suitable sheds for machinery should be provided, and fruit, vegetables, and flowers should be grown. The three small paddocks could be sown to barley, rape, lucerne, maize, &c., for feeding purposes. The returns should be from the garden, £10; 600 bags of wheat at 10s., £300; 360 bags oats at 3s. 6d., £99; 50 sheep, wool at 6s., £15; 40 lambs, wool at 8s., £16; eight cows, 1,680lbs. butter at 9d., £63; sale of eight cows, £12; pigs, £20; two horses, £40; poultry, 1,600doz. eggs at 8d., £53 6s. 8d.; geese and roosters, £10; a total of £638 6s. 8d. In addition to this, 30 tons of hay and 20 tons pea straw should be produced. Expenditure would include 6 tons manure, £25 10s.; seed wheat, 40 bags, £20; oat seed, £4 2s. 6d.; pea seed, £5; other seeds, £5; wheat for fowls, £12 10s.; wages, one man at 25s. per week, £65; a total of £137.

Mr. B. Wundersitz would crop 150 acres with wheat, 10 or 15 acres with oats, fallow 150 acres, and graze 150 acres. The remaining area could be used for lucerne, permanent grass, or orchard, according to the circumstances. The stock should include five working horses, one lighter animal, six or eight milking cows, a few pigs, 25 ration sheep, and 100 or 200 fowls. Overstocking, however, should be avoided.

Mr. G. Hill would enclose the area with a fence consisting of posts 5yds. apart, with five plain wires, and one barbed wire on top. He would then divide it into three 150-acre paddocks, 50 acres being left for grass, timber, &c. Buildings should consist of a homestead, a galvanized iron barn, stable of timber and straw for seven horses, and a galvanized iron shed for implements. A 5-ton wagon, 6ft. damp weather stripper, winnower with elevator and transport, 15-disc drill, five-furrow stump-jump plough, six harrows, one heavy and one light dray, binder, horse rake, engine, chaffcutter, and a buggy would be required. One hundred and fifty acres could be cropped with wheat annually, 120 acres should be fallowed, 20 acres sown to oats, and 10 acres to peas, the third paddock being left for grazing; 150 sheep, seven dairy cows, two breeding sows, 100 fowls, in addition to two ponies and three or four foals, which could be bred annually, and heifer calves from the best of the cows could also be kept. Water should be provided in every paddock. The only outside labor required would be for winnowing, and the sale of cocky chaff should return sufficient to pay the wages.

Mr. S. Beavis assumed that the farm in question was situated on the right bank of the River Murray, between Mannum and Murray Bridge, with a river frontage of about 70 chains. Suitable trees for shelter should be left in the corners of the paddocks. Walls and rafters of cow sheds, stables, pig styes, &c., could be made from split butts of pines. The site for the homestead should be very carefully selected. A large underground tank, a 30ft. or 40ft. well, and windmill should be adjacent. While irrigation from the river, where there were high cliffs, was practically impossible without a powerful pumping plant, the low-lying lagoons, or billabongs, were extremely fertile. About 3 acres of the farm should be planted to fruit trees, vines, and vegetables, mangold wurzels, &c. Alongside, an area of about 20 acres could be fenced, and on this two or three good Alderney cows and a hack and buggy horse could be run. Four paddocks of 100 acres should be fenced. Two of these should be cropped each year, and two cropped and fallowed alternately; on these 100 good sheep could be kept. An average return of 16bush. per acre could be expected, which would sell for £530; 100 sheep should return £30; eggs and surplus dairy produce, £40; a total of £600. Of the remaining area 10 or 12 acres should be sown for hay, and 70 acres used for paddocking the draught stock. The net income should be about £500 annually.

Ironbank, August 16.

(Average annual rainfall, 33in. to 34in.)

PRESENT.—Messrs. C. Morgan (chair), R. Coats, W. Slater, E. Coats, W. Coats (Hon. Sec.), and four visitors.

STRAWBERRIES.—With regard to replanting land with strawberries, Mr. C. Morgan recommended breaking up the land and planting it with field peas after the first plants died out. The next year the soil could be cultivated and manured, and strawberries again planted. He had tried this four years ago, and the results had been satisfactory.

Kanmantoo, August 9.

(Average annual rainfall, 17·90in.)

PRESENT.—Messrs. T. Critchley (chair), T. Mills, H. Downing, E. Shepherd, A. Mills, R. Critchley, A. Stewart, W. C. Mills, W. Downing, R. Talbot, W. G. Johncock, H. R. Shepherd (Hon. Sec.), and one visitor.

POULTRY.—Mr. W. G. Johncock read a paper, from which the following is taken:—"I have kept Minorcas, Brown Leghorns, White Leghorns, Silver and White Wyandottes, Black Spanish, and Buff Orpingtons. My experience has been that the White Leghorns are the best layers, and that for an all-round fowl the Silver Wyandottes are the best of those I have tried. The White Leghorn is very hardy and the chickens are not hard to rear. They grow and mature early, and will commence laying at from five to six months old without forcing. I favor hatching chicks, if possible, in the months of July, August, and September. Unless hatched very late, pullets always, or nearly so, go through a light moult at the usual moulting time, in February or March. If hatched during the months I have named they moult at the usual time, and, being young, with proper attention, recover from the moult and commence to lay again before the wet and cold weather sets in, and will, in most cases, lay right through the winter, when eggs are at the top market value. Always keep the pure blood of any breed that is fancied. If one already has the old barndoor fowl, my advice is to change them as soon as possible, no matter whether one intends keeping six or 60. It is a mistake to think that by having a pure-bred rooster in the yard one can breed up a strain of first-class fowls, for while the stock might be improved, it will be a slow process to get them up to the standard of the best fowls of to-day. Purchase a cockerel and five or six second-year hens from a reliable breeder. Both male and female should be of medium size. The male bird should be bold, vigorous, and full of life, and have a bright red fiery eye. Avoid a bird with a light-colored eye if possible. It should not have too much comb, but the comb should stand erect. Good clean legs, free from any sign of scale, should be looked for. The hens should have fine bright red combs and wattles, red eyes, and good clean legs. The body of the bird should be well balanced, heaviest at the back for preference. The shoulders should be wide and taper back to the tail. I favor the Silver Wyandottes for a second strain, because they, as a rule, are good winter layers, providing they are not kept until too old. It is necessary to have some pullets every year to replace the old stock. I have found the Silver Wyandottes payable for winter laying. As the warm weather comes along they go broody. They are very quiet when sitting and can be placed on a nest anywhere, and removed so that the eggs can be tested. They are also a good table bird. The young male birds sell well, and if fed well, are fit for market at about five months old. One disadvantage, in many cases with the Silver Wyandotte hens, is that they leave their chicks too young. I have had them start to lay again after hatching when their chicks have been a month old. The food of the laying hen should be of the best. Where fowls are allowed to run over an area, as they are on most farms, two feeds a day are sufficient, as they pick up food about haystacks or where stock are fed. Bran mash, consisting of about two parts bran and one part pollard, mixed with the gravy from some boiled meat, could be given in the morning. Gravy from the carcass of the rabbit serves the purpose splendidly, as does also the meat itself well boiled. Give this two or three times a week. The hens do well on milk given in moderation. My experience with the other breeds mentioned has not been so favorable as with the White Leghorns and the Silver Wyandottes. The Minorcas and Black Spanish are fair layers, and produce fine large eggs, but a good White Leghorn hen will lay 30 per cent. more eggs as a rule. The Brown Leghorns are fair layers, but are not equal to the Whites. The Buff Orpingtons are the worst fowls I have ever had any experience with. Sell the hens just before they moult after they are two years old. Mark each season's chicks with a web punch, or aluminium rings for the legs. I am thoroughly convinced that poultry will amply repay any trouble, and that with proper care and attention they are a valuable asset to the farmer. For several years we have been selling wheat at 3s. 6d. to 4s. per bushel, and I have proved that that which I have fed to poultry has returned me 7s. to 8s. per bushel." Members thought sulphur and kerosine the best remedy for scaly legs.

MacGillivray, August 12.

(Average annual rainfall, 19in. to 20in.)

Present.—Messrs. R. Wheaton (chair), H. Ayris, D. Lade, A. J. Nicholls, H. E. Petras, A. Stirling, jun., A. Sands, H. J. Wiadrowski, H. C. Williams (Hon. Sec.), and one visitor.

Trolly Wheels and Tyres.—In a short paper on this subject, Mr. Stirling stated that he had placed the hind wheels of his trolly on the front axles and put still larger wheels on the back axles, thus raising the vehicle 4in. He considered that this alteration reduced the draught by about one ton. Tyres 4in. and 4½in. in width were quite sufficient for the roads in this district, and he thought that the vehicle with tyres of this width, when loaded to its full capacity allowed by the "Width of Tyres Act," would provide a heavier load than could be comfortably drawn over sandy roads. For use in the sandy country in the interior, Mr. Ayris had found the 7ft. wheel with a 6in. or 7in. tyre the most suitable. Mr. Nicholls favored wide tyres with relatively light felloes. It was an advantage to have the latter convex if carting were being done in sandy country, as this enabled the wheel to free itself better. The Chairman thought that whilst the wide tyres were most suitable on softer tracks, they were considerably more trouble than the narrow tyres amongst stumps.

Meadows, August 11.

(Average annual rainfall, 35·52in.)

Present.—Messrs. G. Ellis (chair), T. B. Brooks, J. Stone, J. Catt, F. Nottage, N. A. Kleemann, W. Phillips, J. N. Williams, E. W. Vickery, G. T. Griggs, F. W. Vickery, A. Y. Ellis, W. J. Stone, S. Smith (Hon. Sec.), and one visitor.

Natural Remedies.—Mr. G. T. Griggs contributed an interesting paper, in which he dealt at length with the value of fresh air, healthful exercise, and temperate habits with reference to feeding, both in man and beast. He touched on many entertaining reminiscences of life on the land in the early days of the State.

Meningie, August 16.

(Average annual rainfall, 18·87in.)

Present.—Messrs. W. H. Mincham (chair), G. Hastings, A. Ayers, T. W. R. Hiscock, R. M. Scott, F. R. Deane, S. Yates, F. W. Newson, H. N. Mincham, L. D. Martin, A. A. Pettet, W. M. Wright (Hon. Sec.), and four visitors.

Colt-Breaking.—In a paper on this subject, Mr. F. W. Newson said the best method of handling a colt was to get the animal into a yard, lassoo it, and pull the rope until the beast either came up or choked down. The noose should then be loosened, and the pulling repeated. If the animal were vicious, its fore leg should be fastened up. If this were ineffective a leg rope should be put on. After a roller and crupper had been put on, a sack should be loosely hung from the D on the latter; this would cure the colt of any tendency to kick at anything that may fall off its back. The ropes should then be taken off and the animal allowed to go: after half an hour it should be again caught and driven until it could be guided with ease. The second day's work should be very similar, but it was necessary to teach the animal to lead. On the third day it should be caught, this time without the aid of the lassoo, and have a saddle and bridle put on. After being let loose for an hour the girths should be tightened, and the operator should mount and dismount a few times. When it became accustomed to this it could most likely be ridden without much trouble. Mr. Hiscock always threw a young horse and then handled its feet, pulled its tail, &c. Members thought patience a great factor in respect to the handling of horses.

Morphett Vale, August 23.

(Average annual rainfall, 23·32in.)

Present.—Messrs. A. C. Pocock (chair), H. V. Sprigg, L. F. Christie, F. Rosenburg, F. W. Crittenden, A. Anderson, S. Pocock, H. O'Sullivan, E. Perry, T. Higgins, W. Goldsmith, and E. E. Hunt (Hon. Sec.).

Greenfeed for Sheep.—The following paper was read by Mr. Goldsmith:—"The farmer with sheep should sow greenfeed every year on his dirty hay land. He should first run the cultivator over it to a depth of about 1½in., then drill with about 1½bush. of Cape barley and 1cwt. of super.; this can be finished before seeding begins. The cultivating leaves the seeds of the weeds on the surface, where they will germinate. If ploughed they would be turned under, where they would remain until worked to the surface again. The barley, being a fast grower, will come away with the weeds and there will soon be a picking for sheep. This can be fed off closely until the other feed gets a start. On account of the land having been once cultivated, the farmer, if he wishes, can fallow weeks later than on other ground. He will secure very profitable returns from his weeds and barley, and clean his land at the same time."

Mount Barker, August 13.

(Average annual rainfall, 30·93in.)

Present.—Messrs. J. Pope (chair), B. Pope, H. Jones, A. Ferguson, W. E. Daddow, W. Pearson, S. J. Bishop. L. Hughes, D. L. G. Monfries, F. Simper, J. Little, F. Follett, A. Boehm, C. Miels, G. and J. Cleggett, J. G. Thomas, A. Liebing, G. Milne, A. B. Blades, Davis, Mapley, H. Coventry, J. Choat, H. Coppin, P. Stephenson, C. Crompton, D. Wollaston, G. Warland, J. Woolley, P. F. Liebelt, J. F. Liebelt, R. Alexander, F. H. Adams, H. N. Bell, B. Stephenson, W. T. Stevenson, E. Schmidke, B. Fidler, R. Hollanby, C. Liebelt, F. von Doussa, J. Wilks, W. Jacobs, J. E. Smith (Hon. Sec.), and four visitors.

Hay.—Mr. H. Jones read the following paper:—"Cereal hay is one of the chief products of this district, and therefore should be worthy of our best attention, but farmers do not give it the consideration that they should. A few years ago it was thought that if the ground were ploughed, hand sown, and harrowed all had been done that was necessary by way of cultivation to procure a crop. Through being cultivated year after year the ground was fast losing its vitality, and the crops were failing for want of plant food. Since the introduction of fertilisers and up-to-date machinery into this State, modern science has done much for the advancement of agriculture, and successful crops can now be grown on land that a few years ago was considered useless for cultivation. In a district such as this, where the holdings are small and continually cropped, it is advisable to combine pea-growing and sheep-fattening with hay-growing to increase the fertility of the soil, and I know of no better method than what is known as the four course rotation. Plants differ in the food they take from the soil. The decay of the roots and stubble of one crop forms the plant food for the succeeding crop. There is also less likelihood of disease than would be the case if the land were cropped yearly with the same cereal. Wheat draws more largely from the soil and from a greater depth than oats. Oats depend largely on the atmosphere for plant food, and therefore can profitably follow a wheat crop. Peas are legumes, and are valuable on account of the nitrogen they store up in the soil, thereby increasing the fertility of the land, and setting free chemical solids contained therein. They can either be harvested or fed to sheep on the land at a fair profit. Take for instance a farm of 100 acres of arable land. Divide this into four paddocks or lots, as the case may be. In lot 1 put oats, in lot 2 wheat, in lot 3 peas, and on lot 4 run sheep. The following year reverse the order, commencing with oats in number four, and sheep in the oat stubble, which will give the best self-sown growth. The value of sheep for destroying weeds and increasing the fertility of soil is not yet fully realised in this district. If we follow this course of rotation we will have a much greater quantity of hay of a better quality. Some farmers are of the opinion that any sort of seed wheat is good enough for hay. This is a great mistake, for only well matured and clean seed should be sown. Wheat should always be pickled to prevent smut. A solution of 1½lbs. of bluestone to 15galls. of water is a good pickle. This should be placed in a cask, and the wheat in a bran bag dipped in this for about five minutes, 1½bush. as a time being immersed, at least a week before sowing. In selecting seed always see that it is clean, true to name, and suitable for hay, and the district. There are many recommended hay wheats, but for this district I advise such wheats as White Tuscan, Golden Drop, Bobs, Comeback, Purple Straw, Le Huguenot, Crossbred 53, and Marshall's No. 3, while for oaten hay there is nothing better than Algerian. The question of manures is one that calls for much discussion, as different soils need different kinds and quantities of manure. Some lack one chemical and some another, therefore, it is only by experimenting that we can tell which is the best for this district. From my own experience I recommend superphosphates for wheat, guano super. for oats, and bone super. or bone dust for peas. We know that the supply of artificial manures applied to the soil is not exhausted in one year, therefore by rotation of crops one manure has a chance to act with the other. The ground should be ploughed to a depth of 5in. or 6in., harrowed down fine to ensure a good seed bed, the seed and manures being then carefully drilled in to a depth of from 1½in. to 2in. In light soils the pressure springs should not be used or the seed will be drilled in too deep. If the drill is fitted with a set of drill harrows there will be no need to harrow after it. The soil grinder should next be passed over the ground to break down the clods and ensure a smooth surface for close cutting with the binder. The amount of seed and manure to drill in should be about 1½bush. of wheat with 1cwt. of superphosphates, 2bush. of oats with 1½cwts. of guano super., and 3bush. of peas with 1½cwts. of bone manure to the acre. Given an average rainfall a good crop of oaten and wheaten hay will result. The hay crops should be cut when the wheat in the ears has reached what is known as the early doughy stage, the grain being full, but soft, and the stalk and the lower flag commencing to lose color. Oaten hay should not be cut until the crop is turning from green to brown. If cut green the hay will be bitter. A great deal depends upon the binder. It should be in perfect order, for in the hands of an experienced man time will be saved both in cutting and handling the hay. Only the best twine should be used, as a cheap and inferior article causes delay. The hay should be stooked as soon after cutting as possible. The stooks should be made by hand, the heads being pressed firmly together. Each stook should contain from 30 to 40 sheaves, according to the size of the sheaf. About three acres of wheat and two of oats should be left to ripen for seed for the following year, and to provide straw for thatching the stack, if not under cover. If any of the stooks are blown down in windy and wet weather they should be put up again as soon as it is fine. An inch of rain will not hurt a crop of well stooked hay. Carting should commence as soon as the grain in the head has become solid or when the straws will break at the knots in the sheaves in the middle of the stook. When stacking in the open the middle of the stack should be built with the heads in, and well gabled for thatching, which should be done with wheaten straw as soon after reaping as possible. A hay shed is a labor saving investment, and will pay for itself in a few years. The object of this paper is not merely to show how to grow and harvest a crop of hay, but also to suggest a system of rotation that will keep the crops free from weeds, and help to build up and maintain the fertility of the soil for further requirements." Mr. G. Cleggett thought it better to allow a crop, especially oats, to lie for a day or so before stooking. He had a crop of peas and wild oats last year, and by feeding these to cows he secured better returns than he would have received had he fed the peas to pigs. Mr. Pearson thought it preferable to stook hay in three rows; the tops being put together, and a space left between the bottoms of the sheaves. White Tuscan made a light hay, hollow, and soft, and it was popular for chaff. He favored King's Early. He would cross harrow the ploughing, and then attach the harrows to the drill. Mr. J. Cleggett had mixed oats and wheat in the proportion of one to two, and the land sown with this returned three tons to the acre. Mr. Simper did not favor early wheats. He thought ploughing should be deep for peas, and shallow for the following crop. Mr. Coppin had cut Algerian oats early, and the grain developed afterwards. He was then troubled with mice in the stack. Mr. Pearson allowed the oats to ripen before cutting them. The Chairman favored Algerian oats, as the Cape oats went down if the crop were at all heavy. The heaviest hay crop he had grown was seeded with white oats, Algerian oats, and Crossbred 53. In reply to questions, Mr. Jones said he preferred half oats and half wheat for chaff. Bearded wheats affected the horses' mouths. Sheaves should be tied as tightly as possible; the hay became loose as it dried. Hay for chaff to be fed in the manger should be cut in the milky stage. Cape oats were not dependable. The feeding off of rank crops should not be tolerated; the patches so treated only became more rank the following year. He favored ploughing to a depth of 6in., or even 8in., if the subsoil would permit.

Port Elliot, August 16.

(Average annual rainfall, 20·33in.)

Present.—Messrs. J. Brown (chair), J. McLeod, H. Green, W. Squires, J. F. Vince, and W. E. Hargreaves (Hon. Sec.).

Strawberries.—Mr. Green mentioned that the strawberry plant only lasted for about four years; it was not advisable to replant the ground until the lapse of four or five years, during which time it should be well manured and sown to peas, beans, or clover. The Hon. Secretary had grown Marguerite and White Chilian strawberries on new land, and after three years ploughed them down, and added stable manure and bonedust. The following year he planted the same bed with White Chilian and Royal Sovereign varieties, and applied super. The first year the plants returned a good crop, but the second year little fruit was secured. Mr. Vince thought strawberries required a stony or gravelly soil. They should be planted on a hill facing the north or east.

Fruit-Drying.—Mr. H. Green read a paper, in which he mentioned that to secure continuous fine weather was one of the chief difficulties in connection with fruit drying. Apricots, peaches, apples, and pears required pitting, peeling, slicing, placing on trays, and sulphuring, if it was desired that the color should be retained. Prunes needed to be dipped in boiling water and caustic potash, or soda, in order to soften the tough skin. Plums were very liable to mould, and should be spread thinly in shallow boxes. Dried fruit should not be kept for more than 12 months, as the absorption of moisture from the atmosphere destroyed the keeping qualities. The opportunities of grubs depositing eggs on the fruit could be considerably reduced by the use of a drying kiln. Too much water should not be applied to trees when the fruit was to be dried. It should not be picked until quite ripe, but one difficulty was that the birds destroyed a good deal of it. In the opinion of the writer, bottling was more satisfactory than canning.

Willunga, August 2.

(Average annual rainfall, 25·98in.)

Present.—Messrs. Pengilly, Binney, Biggs, and Hughes (Hon. Sec.).

Dipping Sheep.—Considerable discussion took place on this subject; the necessity for it was admitted by all, and members were agreed as to the value of the practice. They considered, however, that greater care should be taken to enforce the Act after notice had been served upon stockowners. Some men conscientiously dipped their sheep, while others appeared to ignore the instructions to do so. Unless all were compelled to carry out the instructions of the stock inspectors it was futile for any to dip. It was considered that owners of dips should be required to supply sheepowners with certificates—these to be forwarded to the Chief Inspector of Stock. This would make it a simple matter to discover those who had ignored the instructions.

[In connection with the above, the Chief Inspector of Stock remarks—" The Inspector for that district has been most assiduous in his efforts to see that all infected sheep are dipped. If the members of the Agricultural Bureau would carry out the suggestion published in the *Journal of Agriculture* about two years ago and form a local vigilance committee, with a view to keeping negligent owners up to the mark they would be rendering good service to their district. Cases of infringing the dipping regulations should be reported to the Stock Department."—Ed.]

Woodside, August 13.

(Average annual rainfall, 31·95in.)

Present.—Messrs. G. J. Sampson (chair), W. King, W. Rollbusch, H. Howell, R W. Kleinschmidt, H. Rollbusch, F. W. Baldock, A. S. Hughes, J. S. Pfeiffer, C. W. Fowler, J Lauterbach, and J. Morcom (Hon. Sec.).

INTENSE CULTIVATION.—In a paper on this subject Mr. Fowler expressed the view that land in this district was capable of supporting a much greater population than was at present occupying it. Conservation of water and irrigation would have their place, and co-operation amongst producers would necessarily become a big factor. From 20 acres to 80 acres, according to the nature of the land, was sufficient to support a family The growth of raisins, currants, and apples, together with dairying, could be profitably undertaken, and bi-products, such as pigs, poultry, and bees would be found to considerably augment the income. He estimated the return from a 40-acre block, intensely cultitivated and irrigated, as follows :—30 tons from 10 acres of grapes at £3 per ton, £90; 2,000bush. apples from 1,000 trees on 10 acres at 2s. per bushel, £250; return from three cows feeding on 10 acres of lucerne or other fodder, £24; 30 tons hay from 10 acres, £120; a total of £484, to which was to be added the value of the bi-products. The writer thought it should be unlawful to cut township allotments into sizes smaller than one acre. Mr. Lauterbach, in discussing the subject, said that in time land intensely cultivated would become exhausted. Mr. Hughes thought it unadvisable to plant vines in this district on account of their susceptibility to frosts. Mr. King thought township blocks should be not smaller than half an acre, and that only one house should be put on each.

SOUTH-EAST DISTRICT.

Kalangadoo, August 9.

(Average annual rainfall, 33in. to 34in.)

SEEDING PREPARATIONS.—Mr. D. W. Tucker contributed a paper. In a district such as this, he said, it was necessary for the farmer to carefully study the soil he had to work on account of the great variation in the nature of the land. Heavy black and red soils required a great deal more working than soils of the lighter class. The former were best broken up in summer, and gone over with the harrows or cultivator and reploughed before seeding. This would keep the weeds well under. Sandy soil, when broken down too fine, did not drain well, and had a tendency to run together; it was best therefore not to break the sod any more than necessary. The selection of implements was an important point; they should not be chosen simply on account of cheapness. He was of the opinion that three acres cropped well would return as much as five acres carelessly treated.

Keith, August 9.

(Average annual rainfall, 19·20in.)

PRESENT.—Messrs. MacIntyre (chair), Tilgner, Fulwood, Redpath, Shannon, and Lock (Hon. Sec.).

AGRICULTURAL LABOR.—The Chairman read a paper, as follows :—" In our State not so much attention has been given to the consideration of this subject as in two, at least, of the other States. But it goes without saying that we should be equally concerned. One approaches the subject with some trepidation, for it is so often dealt with in other circles than that to which we belong, and in an atmosphere that does not make the issue to be seen clearly in all its importance. It is evident that every man who requires the assistance of others to work his land is interested in this question, be his holding large or small. It is natural that one should begin with the labor required to deal with scrub lands, if the holding is one in a newly settled district, such as this, where the first step is mullenising the timber or rolling down the mallee scrub. This work is best done by contract, which, with the rates now prevailing, enables a man to earn good money. The fixing of rates for particular areas must be determined—(1) by the kind of timber to be dealt with; (2) and the way in which the owner wishes it to be done. To prevent misunderstanding, and to ensure the job being properly carried out, it is always well to have the conditions of the contract written out beforehand. An inspection of the work as it is being proceeded with is also desirable with the same end in view. In the case of rolling mallee where the scrub has to go under the roller, these preliminaries are perhaps not so necessary. In the next stage, *i.e.*, clearing by burning off, the contract system is again the best. A man on contract will not be unwilling to go out for an hour after dark to attend his fires, where this could not be expected of a man on weekly wages. The contractor knows how much advantage is gained by an hour a night given to his fires. The third stage—that of fencing—is often work that is best done by contract. Here, too, the price must be regulated by the kind of fence required and the nature of the sinking, as far as that can be ascertained. What has been said as to the fairness of the contract system in clearing and fencing is equally applicable to the case of well-sinking, where payment by the foot is the best. It is, however, when these stages are passed that the most difficult ones are reached, viz., reasonable payment for the many other kinds of work on the farm. Owing to the man on the land dealing at firsthand with the forces of nature in the soil, in the seasons, and in working and grazing animals it is impossible for him to regulate the hours of labor as it can be done in mechanical industries. Then the fact that so much of the work is not continuous or arduous is another source of difficulty in trying to arrange the hours of work to a nicety; *e.g.*, during the ploughing and seeding the feeding and grooming of the team before breakfast has a set off in the two hours' spell during dinner. It has to be remembered as well that in our summer climate long spells in harvest are necessary, both for men and horses. Coming to the case of those dairying, something of the same applies. The cow's habits have to be studied, for she refuses to give way to twentieth century progress, and will not be hurried. In trying to arrive at what is a fair rate of wages, equal difficulties lie in the way. There is first of all the variation of the yield of the land, due to the season and its inherent quality. There is the variation in the price of most kinds of primary produce, especially wheat. The distance over which produce has to be carted to the market or railway; in one case it may be 2 miles, another 20 miles. Then there is the important question in the difference of men to be employed—one man may be more careful in the management of his team. Again, a man who is intelligent and understands the working of modern implements is worth more than a man who is without much of either. Everyone knows how much loss of money and time is due to want of skill and care in the using of tools and implements. In order to get experienced men for the more important work, and where so much valuable property is at stake, as well as for taking the responsibility of leading the work, I favor the engagement of a married man for a period of, say, a year. It would be necessary in this case to provide him with a home, along with which he should have land for a garden and fowls, &c. On a place where several young men are employed, arrangements might be made for them boarding with him. The quarters for the men should be comfortable and clean. An inspection of them from time to time would be in the interests of everyone." Members generally agreed that the regulation of the hours of labor on the farm was not practicable.

Kybybolite, August 21.

(Average annual rainfall, 22in.)

Present.—Messrs. A. Bradley (chair), F. C. Lacey, G. H. Hahn, G. S. Jenkins, H. B. Schinckel, E. W. Duffield, L. Smith, A. Bradley, jun., S. Alcock, J. Davis, C. H. Scholz, A. R. Scholz, E. C. H. Schinckel (Hon. Sec.), and four visitors.

The Points of the Horse.—Mr. W. J. Colebatch, B.Sc., Agric., M.R.C.V.S. (Superintendent of Agriculture in the South-East), gave a practical demonstration on the points of a horse. He said—"Most farmers possess a fair knowledge of the general characters to be looked for in a horse of good quality, but few would care to undertake the responsibilities of show-ring judging, or to officiate in any capacity in which their knowledge of the points of a horse would be brought under the searchlight of public criticism. This may be due to natural reluctance to publicity or to a want of confidence, which may be attributed in some cases to a want of method or system in the process of judging. No matter what the circumstances may be—whether the examination be made in the show ring or sale yard, the aim should be to adopt some definite and thorough system of working. Once adopted, the method should, as far as possible, be rigidly adhered to. In many instances, of course, circumstances will not permit of a complete examination and only a cursory survey may be possible, but even in such cases the man who has habitually trained his powers of observation on a well-arranged plan will be in a better position than those less well schooled. In the general examination of either light or heavy horses the most important points to be considered are conformation, quality, and action. In judging draught horses, the eye needs to be specially keen to detect defects on account of the thicker skin, coarser hair, and the 'feathered' shanks. Furthermore, heavy breeds, owing to their lymphatic temperament, are more prone to lay on fat and so round off the inequalities of form than are the lighter types. Such pampering of draughts should be carefully guarded against, as the lack of symmetry becomes all too rapidly apparent when the animal is again reduced to healthy, working condition. In order to grasp the real significance of the importance of conformation, it is essential to mark the extent to which bone and muscle respectively contribute to the external form or outline. The shape of the head is determined by its bony skeleton, the neck, on the other hand, consists chiefly of muscle and ligaments. The shoulder and chest are formed mainly of bony structures, but muscles help to fill up the depressions. The arm and forearm are shaped by muscles, and from the knee downwards the form is dependent on bones and tendons. From the loins to the buttocks and down to the point of the hock the muscular development is very marked, and it is here that we find located the propelling muscles of the body. Whereas the forequarters are relatively bare, the hindquarters, croup, and thigh are very largely composed of powerful bundles of muscular tissue. The manner in which the horse distributes the weight whilst standing asleep indicates that the forelegs are chiefly weight-carriers, and this theory is further supported by the loose attachment of the shoulder plates as compared with the snug ball and socket joint at the hip, and also by the manner in which the fore end of the trunk is suspended, as it were, in a muscular sling between the blades. Below the point of the hock the outline of the limb is dependent on osseous and tendinous structures, as in the case of the fore leg. In light horses, where speed and staying power are of pre-eminent importance, the general form should be of neat build, symmetrical, and well proportioned. The skin should be smooth and close-fitting, and should be well covered with fine quality hair. The importance of a good skin is better appreciated when it is realised that the lining membranes of the food canal develop from the same embryonic layer as the third stratum of the skin. It is not, therefore, illogical to draw deductions as to the digesting and assimilating capacities of an animal from the character of its external integument. Draught horses should be squarely built, even, heavily muscled, and comparatively low set. For heavy traction weight of carcass is of special importance. Length rather than bulk of muscle is to be looked for in light horses. Muscles are composed of fine parallel contractile fibres, and the longer these fibres the greater the range of movement. Hence, the muscles of greatest length are to be sought after in animals required for fast work, whereas in the heavy breeds the short, stout, thick muscles that denote power are in demand. Whilst the source of muscular energy should differ in character, according to the purpose in view, the distance through which the force is transmitted should invariably be short, as the loss in transference increases with the distance traversed. It follows from what has been said that the forearm in light horses should be as long as possible, with due regard to proportion, whilst in draughts it should be short, stout, and thick. In both types the cannon bones should be short. Whilst speaking of the muscles, it may be pointed out that the forearm and lower thigh, or gaskin, are almost entirely muscular, and since there is little tendency at any time for fat to accumulate in these regions their development may be accepted as a guide in the formation of an opinion as to the general muscular condition of an animal in useful condition. Reference to these parts may, therefore, be useful as a means of picking out useful types from a mob of low-conditioned horses, or of rejecting likely animals that have been fed up for sale. Consideration should also be given to the phrase 'flat bone,' which is so commonly employed to describe desirable conformation in the region of either the fore or hind cannons. The exact meaning is very often misunderstood. The cannon bone in the fore leg is only flat on one face, and that the posterior one, which is so covered by soft structures as to be unobservable from the outside. The front and side faces of the bone are distinctly rounded, and the curvature in the hind cannons is still greater. The phrase, therefore, cannot be interpreted literally. It has reference to the flat appearance of the lateral faces of the region between the knee (or hock) and fetlock joints, and this flatness is determined mainly by the manner in which the tendons at the back of the legs stand out with sharply defined edges from the back of the bone. This type of conformation is desirable for the reason that there is generally associated with it a hard dense quality of bone, clean cord-like tendons, and a minimum of subcutaneous connective tissue." The special features of the particular regions were then described in greater detail. Members then inspected the crops on the Government Farm, and were agreeably surprised at the growth these showed, especially in the case of the wheat and kale.

Millicent, July 8.

(Average annual rainfall, 29·25in.)

PRESENT.—Messrs. Mullins (chair), Holzgrefe, Bowering, Hart, Edgecombe, Serle, Downs, Major, and Day (Hon. Sec.).

BERSEEM.—Mr. Holzgrefe reported that the berseem (Egyptian clover), which he had carefully sown, had not made satisfactory headway, and it had not returned any bulk of feed. Mellilotus was far superior to it as a fodder. Mr. Mullins also stated that it had not been a success with him.

TREE-PLANTING.—Some discussion took place on tree-planting. Mr. Holzgrefe recommended the utilisation of poor land by planting suitable trees, which would in time be valuable as shelter for stock and also for firewood. He had found that trees obtained from a nursery did not do well when transplanted in an open situation. Mr. Hart advised farmers to grow their own trees from seed. Remarkable pines and blue gums were mentioned as suitable for this district.

Millicent, August 12.

(Average annual rainfall, 29·25in.)

PRESENT.—Messrs. J. J. Mullins (chair), H. F. L. Holzgrefe, G. Major, J. Bowering, W. Downs, and H. Day (Hon. Sec.).

PROPOSED EXPERIMENTAL FARM.—Mr. Holzgrefe drew attention to the fact that a vast area of land was being reclaimed in the district, and expressed the view that the Government should establish an experimental farm in the locality immediately. The people who would settle on the reclaimed lands in the South-East in the near future would be newcomers for the most part, and the farm would be of immense benefit to them, as well as a help to the older settlers. Even now farmers on the Millicent flats experienced occasional failures owing to not knowing the exact requirements of the soil. The soil on the Wyrie was typical of large areas of unoccupied land in the South-East. It was decided, on the motion of Messrs. Holzgrefe and Downs, that the Branch take the necessary steps to urge the Government to select a site on the drained country suitable for the purposes of an experimental farm, and that the Lucindale, Penola, and Kalangadoo Branches be asked to co-operate in the movement.

Mount Gambier, August 9.

(Average annual rainfall, 32in.)

PRESENT.—Messrs. D. Pritchard (chair), A. Sassanowsky, E. F. Crouch, J. F. Holloway, J. Bottrill, H. Kennedy, H. Wheeler, E. F. Schlegel, W. J. Sutton, C. Major, H. Buck, J. Watson, J. C. Ruwoldt, G. and D. Collins (Hon. Sec.)

DAIRYING.—Mr. E. F. Crouch delivered an address, in which he stated that there was no disadvantage in dehorning cows whilst they were in milk, and it would be found that the animals were afterwards much easier to handle and less likely to damage one another. In travelling round the district he had observed generally a poor class of cows, and it would be a good thing if the dairy factories would purchase good bulls for the dual purposes of beef and milk. There were good cattle for both. For example, the milking strain of Shorthorn and the Lincoln Red. In England at the present time there was a good demand for the Lincoln Red. and dairy people were giving as much as 50 guineas for a bull calf 8 or 9 months old. If a dairy factory purchased a bull it could be placed in charge of some shareholder, and the shareholders could have the use of it on application on any terms fixed. If that were done he would suggest that any man who had a cow of a particularly good test should be allowed to have that cow served by the bull at a lower cost than was charged for an inferior animal That would be an encouragement to keep a better class of cows. If all the factories went in for the same system these bulls could be exchanged from time to time, and if all the receipts from the bulls were put into a fund, this would be available for the purchase of other bulls when required. He then urged the necessity for care in feeding young calves, and read an extract from an English publication relating to experiments with grasses at Woburn. Mr Sassanowsky agreed as to the advisability of dehorning cattle. The suggestion that dairy factories should purchase bulls was an excellent one.

Penola. August 2.

(Average annual rainfall, 26·78in.)

Present.—Messrs. A. E. Lampe (chair), J. T. Williams, J. Darwent, J. Warner, D. Adamson, P. H. Kilsby, W. Miller, D. A. Fullerton, S. L. Norman, J. Redman, L. W. Peake, S. Ockley (Hon. Sec.), and two visitors.

Draught Horses.—Mr. P. H. Kilsby read a paper, as follows:—"Farmers should take particular care when procuring draught horses for the farm. It is much better to buy mares than geldings. As farmers in this part finish seeding about August, that gives the mare time to have her foal, and get into condition for the harvest. Some buy a gelding because they can get him at 3 years old for £30, and refuse to give an extra £10 for a good mare at the same age. When the gelding is about 8 years old he is worth about £20, and the mare £30, allowing the same depreciation on both. But in the five years the mare might produce at least three foals. Use only the best sire procurable, regardless of cost, as the high priced horse is the cheaper in the long run. For this district I prefer the heavy draught, both for farm and contract work, and there is always a better demand for these, even when the market is dull. Farmers should always try to improve their horses. If one only has a medium mare, mate her with the heaviest sire procurable. I believe in working a mare lightly up till within three weeks of foaling, there will then be very little trouble. It is a great mistake to let her get too fat. It is also a bad practice to take the mare away from her companions a few days before foaling, as she frets for them. Put another mare in with her to keep her company in a warm paddock at least a week before foaling. I always catch my foals when about a week old, teach them to lead, tie up in the stall, and pick up their feet. If this is properly done the foals will never forget it, and at harvest time the foals can be tied up or taken to the harvesting paddock. It is a good plan to feed them together when they are about 7 months old. Put them in a yard at dinner time, do not allow them to have a drink from their mothers, allow them water and feed, and to go with their mothers at night. Wean them at eight months. When turned out, they will soon forget their mothers. I always make it a practice to save a small paddock for weaning time, and thus ensure a good supply of natural grass. This, together with a good feed of chaff and bran twice a day, should carry them well up to spring. A colt should not be castrated before 18 months old, as early castration tends to rob it of a certain amount of vitality, and when left the animal has a chance to form a good crest, which looks very becoming on a gelding. Breaking in can be done at 2½ years old, providing only light work is done the first year. It is well to break in two at the same time, and work them half a day each. If wanted for heavy work 3 years to 4 years is best, but for ordinary farm work 2½ years is preferable, as at the earlier age they are more tractable, and easier to handle, and have not forgotten the attention given them when foals. Great care should be taken of the horse's shoulders at this stage. As soon as possible after working they should be washed well with cold water, with a little salt added, and then with a wattle-bark solution. This keeps the shoulders from cracking and blistering, and hardens the skin. The collar must be of a good fit, and should be brushed well before being used. I recommend putting a filly to the sire at 2 years, as this minimises the risk. The bones have not become set, as is the case with a filly a year or two older. If this procedure were more generally adhered to a great saving to breeders would result, as the percentage of losses among draught mares is very great, which is caused very often by allowing the mares to get to the age of 5 or 6 before commencing to breed. My experience in watering draught horses has led me to the conclusion that it is as well to allow a horse to have a good drink as soon as work is finished. I have never known of any ill effects resulting from this. Regarding the feeding of farm horses, give them a 5-gall. drum each, with some oats and bran or boiled barley added, for breakfast. They should be fed at least one and a half hours before work. At the mid-day meal give more oats than before, and at night, when they come in from work, a little bran should be put in, and they should be made to clean up any chaff that may have been left. Then put in a small feed, and at 9 o'clock give them enough for a good feed. Horses should be well bedded down. Give them plenty of good dry straw, they need a good soft bed, they should be rugged all the winter, even if they are kept in the stable. I believe in rugging horses, as it keeps them warm, gives them a fine coat, and they do not require so much grooming. The stables should be cleaned out every day. Always keep rock salt in the feed box. Horses require two packets of salts at the week end to keep their blood in order. I recommend all farmers to keep a few tons of chaff over for the harvest, as horses do not do well on new hay, and waste more than they eat. They will not work on the natural feed alone, and it is not wise to let them go down in condition at this time of the year. All harness should be overhauled, the collars being given special attention, as horses are more likely to get sore shoulders at harvest time than at any time of the year."

Mr. Adamson asked the opinion of members with regard to a stable floor, and Mr. Kilsby recommended split slabs 4in. wide and 6ft. long; but particularised that they should be split and not sawn, and then horses would not slip on them. Mr. Fullerton recommended straw bedding to minimise the slipping. Mr. Williams advised screened gravel with a good slope, well tamped with plenty of sand, and top dressed with hot tar. It was advisable to repair every little hole as soon as it appeared. Drainage was most important. Mr. S. L. Norman said temperament of the sire was most important He agreed that farmers generally should improve their stock. His ideal was an animal with 10in. bone and 16 hands in height. He had a great opinion of the Suffolk-Clydesdale; but there was difficulty with the mare from the cross. The Secretary said they should consider the class of land that was to be worked and the work they had to do; where they were not always in use on the land, lighter horses could be used. Mr. Williams had had a lot to do with light horses, and, though they might have a slightly better crest if left till 2 years old before being castrated, it did not make any difference to their stamina, and when one considered the greater difficulty in handling them at the older age, he preferred castration at 4 months old. That might not apply to draught horses, but it was his opinion with regard to light. Mr. J. Darwent said trouble often arose from castrating too close. He believed that if, when castrating, they took out the main testicle and left the button they would find that their horses would have more pluck and endurance and better carriage. Mr. Kilsby, in reply, said he always handled his foals when a few days old and docked them then, as he found they lost less blood than at marking time, when the one loss was sufficient.

Tatiara, August 2.

(Average annual rainfall, 19in.)

Present.—Messrs. Sullivan (chair), P. Low, C. Stoude, E. Prescott, T. Stanton, A. Fisher, and T. L. Truman (Hon. Sec.).

Sheep Skins.—Mr. Stanton read a paper as follows:—"The value of the average sheep skin in the Adelaide market is about 7s.; that is if it is well dried and taken care of. The same skin, badly cared for, is worth only about 3s. The average farmer kills 50 sheep in a year; 50 skins at 7s. equals £17 10s.; the same number of skins badly cared for at 3s. equals £7 10s.; showing a loss of £10 on every 50 skins where they are not properly treated. The number of skins marketed each week is about 12,000, which at 7s. are valued at £4,200, and at 3s. £1,800, showing a loss of £2,400 if they are poorly treated. A good deal of this loss can be avoided. The farmer who keeps skins for longer than three weeks should have a supply of skin wash ready mixed in an oil tin. As soon as the skin is taken off the sheep, spread it out flat, and give it a good wash all over on the pelt side, then hang it longways on a rail in a shed. Fold the tail in under the skin, cut off the feet, and hang weights of about 1lb. on each leg. Inspect the skin two or three times while drying and turn out any pieces that may be folded in, so that they can dry. When the skins are thoroughly dry, place them in a dry, clean place, pelt to pelt and wool to wool. If forwarding to market, fold the skin double, longways, wool outwards, turn in the head part, and do not make too heavy a bundle." Members were divided in opinion as to the value of skin washes. Some thought the writer's estimate of the average price of skins too high.

Wirrega, August 9.

(Average annual rainfall, 19in. to 20in.)

Present.—Messrs. H. Exton, P. Prime, C., F., and E. Meier, F. and L. Densley, J. Green, H. Laurenti, L. Pitman, L. Cook (Hon. Sec.), and a number of visitors.

Fallowing.—Mr. Williams, in a short paper, said it would not pay to fallow new ground. He did not think good crops could be grown until the majority of broom stumps had been destroyed, and this would take two or three years. He preferred the mouldboard plough. Fallow should be ploughed to a depth of about 4in. Shoots should be cut, raked up, and burned. Following this, the land should be cultivated after a good rain. Harrowing would serve the purpose on light sandy soil. Members generally favored fallowing to a depth of 4in. Some preferred the disc plough, as it cut shoots and lateral roots, and chopped out the broom bush, whilst others favored the mouldboard implement. This pulled out more stumps, left the ground in a better condition, and hence, the fallow was better. It was deemed inadvisable to work the lighter lands much before summer, especially if there were no trouble with weeds.

Minister of Agriculture.

POINTS FOR PRODUCERS.

Government Produce Department.

That the operations of the Government Produce Department does not escape the attention of interested parties abroad is shown by the following paragraph clipped from *The Live Stock Journal*:—"The South Australian Government Produce Works is taking an important part in the world's meat supplies. For some time past the department has been treating boneless beef killed by private butchers, but the ready sale of this article and the great demand for oversea markets has led to the Government erecting a slaughter-house at their works in Port Adelaide. This slaughter-house has a capacity of something like 60 carcasses per day. Considerable quantities of frozen lamb and mutton are already shipped to London, and between 100,000 and 200,000 carcasses are dealt with in this manner. Official figures taken from the last Statistical Register give the head of cattle as being 393,566, and for sheep as 6,171,907.

South Australian Sheep.

South Australia, states *The Live Stock Journal*, still holds the record for abnormal length of staple, for recently a lock of wool 4ft. 6in. in length was exhibited in Adelaide, and is quite unsurpassed by anything to be met with or heard of in any other part of Australia. A case has been cited recently of a fleece of three years' growth raised on the hot plains of Central Queensland. It was a South Australian-bred sheep, and the constitution for which South Australian sheep are so well noted is held responsible for the retention of this growth during three hot summers.

Farmers at Roseworthy.

On Monday, September 16th, about 160 producers availed themselves of the invitation of the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) to attend the annual inspection of Roseworthy College and grounds. In addition to the Minister there were present Professor A. J. Perkins (Principal of the College), the Secretary to the Minister (Mr. W. L. Summers), the Secretary of the Advisory Board (Mr. G. G. Nicholls), the Dairy Expert (Mr. P. H. Suter), and the various officers connected with the College. Needless to say the crops were in a very backward condition, and presented a striking contrast to what has been seen at the College in previous more favorable seasons.

Nevertheless the visitors, who were afforded every information possible by the Principal and his assistants, spent a most enjoyable day and gained a great deal of useful information. Particular interest was evinced in the berseem or Egyptian clover plots, which this year have proved a veritable godsend in the way of providing fodder for the dairy stock. Some of the plots had been cut twice, and its vigorous growth testified its value in a season like the present. At the conclusion of the inspection the Minister briefly addressed those present, and on his initiative hearty cheers were given for Professor Perkins.

Australasian Fruitgrowers' Conference.

The annual conference of the Fruitgrowers' Association of Australasia will be held in Adelaide this month. The inter-State delegates will arrive on October 21st, and, with the assistance of the Minister of Agriculture (Hon. T. Pascoe), an attractive programme has been arranged for their entertainment. On their arrival at Murray Bridge on the Tuesday they will be met by the Director of Irrigation (Mr. S. McIntosh) and members of the executive of the South Australian Fruitgrowers' and Market Gardeners' Association and conveyed by launch to inspect the irrigation and reclamation works in the vicinity of Murray Bridge. The conference will be opened by the Minister of Agriculture in Adelaide on the Wednesday morning, and in the afternoon the visitors will be taken for a trip along the Torrens Valley. In the evening it is proposed to hold a social. After a morning session on Thursday there will be a drive through the Adelaide hills, by way of Norton's Summit, Mount Lofty, and Belair. On Friday morning the business sittings will be resumed, and in the afternoon, at the invitation of the Government, the visitors will inspect the Produce Depot at Port Adelaide, and have a trip to the Outer Harbor. The conference business will be concluded on Saturday, if not earlier, and it is intended to make a visit to the Government Experimental Orchard at Coromandel Valley. It is anticipated that each of the Australian States and New Zealand will be represented at the conference.

Adelaide Wool Sales.

The first of the 1913 series of wool sales was held in Adelaide on Thursday, September 18th. The catalogues comprised 27,581 bales, which is a record for an inaugural offering of the season. There was a large attendance of buyers, all sections with the exception of America being well represented, and competition was animated. For all good wools the market was from par to 5 per cent. above last year's opening rates, but in regard to the heavier-conditioned lots the improvement was not so marked. Lambs' wool, especially the good lines, ranged from 1d. to 2d. a pound higher than at the first sale in 1912. A feature of the sale was the activity of the French buyers, the wools, which at the opening almost invariably come from the back country, especially suiting their requirements. Strong competition for good wool was also evinced by Sydney buyers, who secured about 1,500 bales, chiefly of the good, shafty, combing wools. Of the total offered 26,756 bales were sold, the highest price realised for greasy Merino being 11¾d.

Lack of Farm Laborers.

Judging from statements appearing in various English agricultural papers the dearth of farm laborers is a problem by no means confined to the Commonwealth. The subject has recently been discussed at meetings of various local agricultural organisations in England. One speaker, at a meeting of the Cumberland and Westmoreland Chamber of Agriculture, expressed the opinion that the solution of the problem was more married servants and the provision of more cottage accommodation.

Care of Farm Machinery.

The expense of farm machinery, says *Campbell's Scientific Farmer*, has steadily increased for a number of years past. The average life of the ordinary farm machine is not what it should be. The adjustments in the machine and the care of it should be just as thorough and painstaking as the adjustment of the harness and care of the horse. Each has a life to give, one animate and the other inanimate. Both will lose money for the man who does not give them proper care. The loss in farm machinery is just one of the big leaks on the farm. To stop it, house and care for the farm machinery.

The Effect of Watery Foods on Milk.

The August issue of *The Journal of the British Board of Agriculture* contains an interesting summary of the literature which has appeared during recent years on the effect of watery food on the production and quality of milk. After quoting the results of several experiments the article proceeds:—"The general view of those who have studied the subject seems to be that excess of drinking water does not appear to have any effect whatever upon either the quantity or quality of milk. Special attention was given to this question in the experiment organised conjointly by the Board and the Agricultural Education Association in 1910. It seems, therefore, unreasonable to expect water administered in any other form to have any effect on the yield and composition of milk. The experiments cited show that there are certain watery foods (such as roots) which appear to have no very pronounced effect on the milk, while others, such as pumpkins, reduce the secretion materially. Still others (brewers' grains) have, by general consent, a marked stimulating effect. It would appear, then, that the water content of the food as such has but little influence on either the quantity or quality of the milk. It is one or more of the other ingredients of the food—not necessarily nutrients in the ordinary sense—which are responsible for the variation in the output and fat content of the milk. It was pointed out in one bulletin that brewers' grains might have a physiological effect resulting in increased flow." In this connection attention is then directed to experiments made by Dr. Hopkins, of Cambridge, from which the following conclusions are drawn :—" 1. That many feeding stuffs have a specific effect on the yield and quality of milk; and (2) that this effect is to be attributed to stimulating substances in the food substances which have physiological rather than nutritive effects, and which are present in foods in small quantities only."

Credit Banks.

Judging, says the *Agricultural Gazette*, from the voluminous reports published month after month on this subject by the International Institute of Agriculture, it would seem that farming is carried on in most European countries mainly by means of borrowed money; also in India and Japan to a less extent. Great Britain, British Colonies, and the United States appear to have managed to conduct farming enterprise without any considerable resort to co-operative credit. The system has spread slightly in England; but the business done by it is the veriest trifle. In Ireland it has made greater headway.

The Man who Wants to be a Farmer.

It is strange, but it is true nevertheless, that the greatest advancement in the line of scientific farming is being made, not by the man who is a farmer by birth and inheritance, but by the man who wants to be a farmer—the man who gets his knowledge first and then proceeds to apply it. There is a great movement on hand for better farming methods, but the initiative is coming from the cities and towns and from the centres of agricultural education. Practical knowledge is a mighty thing, but when it is not backed by scientific information it is of little worth. It is little better than theoretical knowledge without practical experience. The best farmer in the world is the one who, having the practical experience, adds the scientific knowledge that tells him why he does things. He is then master of the situation. The next best farmer is the man who wants to be a farmer and begins with a foundation of scientific knowledge, then adds experience. His experience may cost him something, but it will not cost him as much as the experiments of the hit-and-miss practical farmer will cost him.—*Campbell's Scientific Farmer.*

Waterproof Cornbags.

The New South Wales Department's Foreman of Works supplied a correspondent with a useful wash for applying to cornbags to render them waterproof. He states stone lime, coarse salt, glue, and fat or oil, mixed in the following proportions, will make a good covering for bagging :—Take 10lbs. lime, slake with boiling water, and strain ; then add 1lb. glue and 1lb. coarse salt, dissolved. To each 4galls. of limewash add 1lb. fat (or oil) ; stir the whole together, and cover for a day before using. This mixture will keep for at least three months if placed in a cask and covered with a bag coated with limewash. To make it waterproof, the usual plan in making a tarpaulin is to give the canvas a cold coat of boiled linseed oil, and, when this has dried, a coat of Stockholm tar. If necessary, give a second coat of tar, and if it should become hard, or show signs of cracking, apply a coat of raw linseed oil.—*The Farm Journal.*

Weed-Infested Lucerne.

Replying to an inquiry *re* weed-infested lucerne, Mr. H. A. Ross writes in the *Agricultural Gazette of New South Wales*—" It is advisable to cut the lucerne together with all the rubbish that may be in the field, with a mower, about this time of the year. The first cutting will be done, of course, when the plants are out in flower. It would be well to let the rubbish lie in the field in preference to carting or raking it off ; this will act as a mulch to the crop."

Processes in the Soil.

There are two great processes going on continually in the soil, which are known to be due to the activities of bacteria—(*a*) The conversion of ammonia and other compounds containing nitrogen, derived from decaying organic matter and nitrogenous fertilisers, into nitrates, the only form in which, so far as we know, plants can utilise the nitrogen. (*b*) The utilisation of free nitrogen of the atmosphere by leguminous plants. Both these processes are greatly facilitated by the presence in the soil of a sufficiency of lime. The application of lime to the soil is one of the oldest methods of treatment known in agriculture. It was apparently employed by the Romans 2,000 years ago. In various European countries it has been practised for many years past.—*Mark Lane Express.*

Sheep for Meat Production.

It is undeniable that the sheep species, both in the lamb stage and when older, furnishes meat of most excellent quality when the animals are suited for this purpose. Therefore the present seems to be an opportune time for stockmen to pay more attention to the raising of sheep for meat production. This Bureau has for a long time recognised the country's lack in this respect, and has taken steps to improve the situation. Through its Animal Husbandry Division sheep-breeding experiments have been in progress for years, the most important of these being the co-operative work with the Wyoming Experiment Station for the purpose of producing a range type of sheep that will be of good mutton form as well as yielding a heavy fleece. These, as well as other experiments with strictly mutton breeds, are still progressing. Finally, it would be in the interest of economy for the people generally to cultivate a greater taste for mutton and lamb, especially the smaller families who require joints of a size that cannot usually be supplied from the larger beef animals. A more insistent demand on the part of the public for mutton and lamb of good quality would no doubt soon lead to an increase of breeding and feeding operations, besides relieving somewhat the present heavy demand for beef and pork in the face of a short supply.—Annual Report, Bureau of Animal Industry, U.S.A. Agricultural Department.

Whitewashing of Fowlhouse Roofs.

The whitewashing of fowlhouses inside is always recommended, but it is almost as important during the summer to have the roof whited also. One can hardly believe the difference it makes to the temperature inside, but try it by placing one hand on a part that is whited and the other on the felt or galvanised iron before whitewashing (of course, when the sun is shining on it). Not only does the reduction in temperature prove a great boon to the birds, but it saves in a measure the shrinking and warping which pulls a roof about so during a hot summer.—G. Parker, in the *Poultry World.*

Sound Stallions and Registration.

Be it for heavy or for light horses, says *The Live Stock Journal*, there is not the slightest doubt that the still quite new scheme launched by the Board of Agriculture in regard to the registration of stallions is being taken up "with avidity," to quote W. S. Gilbert, by the possessors of sound horses. From the official report upon the work of the Light Horse Breeding Advisory Council, one gleans that, so far, 825 stallions have been registered as against 715 in 1912, and, as this number is exclusive of stallions registered in Scotland, the returns must be considered encouraging. The Board, one notes further, has decided to amend their registration regulations so as to allow two appeals instead of one, and also to confine the certificate of the examining veterinary surgeon to the soundness of the stallion, the question of its suitability being left for determination, if necessary, by a conformation judge appointed by the Board.

Imports and Exports of Fruits, Plants, Etc.

During the month of August, 1913, 21,221bush. of fresh fruits, 13,165 bags of potatoes, 287 bags of onions, 8bush. of sweet potatoes, and 82pkgs. of trees and plants, etc., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885; 68bush. of bananas (over-ripe) and 1 parcel of plants (containing vines) were destroyed. Under the same Act, 22 bags of potatoes were exported to West Australia. Under the Federal Commerce Act, 2,350pkgs. of fresh fruits, 2,450pkgs. of dried fruit, 36pkgs. of preserved fruit, 14pkgs. of honey, and 12pkgs. of jam were exported to oversea markets during the same period. These were distributed as follows:—For London, 187 cases oranges, 1,764pkgs. of dried fruit, 12pkgs. of jam, and 3pkgs. of honey; for Bremen, 1 case of oranges; for Genoa, 11pkgs. of honey; for India and the East, 100 cases of apples and 35pkgs. of preserved fruit; for South Africa, 686pkgs. of dried fruit; for New Zealand, 1,209 cases of oranges, 853 cases of lemons, 1pkg. of preserved fruit, and 3pkgs. plants. Under the Federal Quarantine Act, 908pkgs. of plants, bulbs, seeds, nuts, etc., were examined and admitted from oversea markets. During the month of September, 1913, 21,852bush. of fresh fruits, 8,463 bags of potatoes, 261 bags of onions, 90pkgs. of Swede turnips, 71bush. of sweet potatoes, 2pkgs. of plants, 198doz. cabbages, and 89pkgs. of trees, were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910; of these, 600bush. of bananas were fumigated, and 54bush. of bananas were destroyed, being over-ripe. Under the Federal Commerce Act, 1,404 cases of fresh fruits, 100pkgs. of honey, 42pkgs. of preserved fruit, and 680pkgs. of dried fruit, were exported to oversea markets during the same period. These were distributed as follows:—For London, 100pkgs. of honey, and 10pkgs. of preserved fruit; for Canada, 400pkgs. of dried fruit; for India, 32pkgs. of preserved fruit; for New Zealand, 1,002 cases of oranges, 402 cases of lemons, and 280pkgs. of dried fruit. Under the Federal Quarantine Act, 761pkgs. of plants, bulbs, seeds, nuts, etc., were examined and admitted from oversea markets.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"E.B.," Truro, has a draught stallion very lame in near hind fetlock for three weeks, with hard wrinkles at back of joint, improves and relapses, especially when standing in the stable ; is being fed high to go on his round.

Reply—The horse has greasy heel, which will be difficult to cure. Give Fowler's solution of arsenic, a tablespoonful twice a day in food for a fortnight, stop for a fortnight, and then repeat ; stop high feeding and give a bran mash daily and hay ; exercise or allow loose in yard. It would do him good to have three or four pints of blood taken from the neck vein. Apply the following lotion daily to the leg :—Flowers of sulphur, ½lb. ; slaked lime, 1lb. ; water, 2 quarts.

"F.M.," Myponga, has a filly that broke out in small lumps like blisters after being overheated.

Reply—This condition is sometimes called nettlerash, and arises from a chill upsetting the digestion ; usually it disappears in a little while without treatment, but an ounce of Epsom salts twice daily in food or water will do good, or half an ounce of flowers of sulphur once a day for a few days in the food.

"P.," had an aged mare in good condition, which he found dead, practically disembowelled, no signs of having been gored or torn ; in foal.

Reply—Most probably a stake was the cause of the condition, but if not, the belly wall gave way after an old-standing rupture ; probably there was an attack of flatulent colic also.

" J. F. W.," Macclesfield, has some bought pigs which do not thrive; he suspects worms and asks for a remedy.

Reply—Very possibly worms are the cause of the want of condition, but it would be well to advise the Chief Inspector of Stock and let one of his officers see the pigs. In the meanwhile let each pig have occasionally in milk two ounces of crushed castor seeds; if there are worms this will shift them, and the pigs will eat them readily. Melon seeds may be used instead. Cinders or charcoal in the feed will be found useful as a regular thing. Most pigs will drink up in their wash a teaspoonful of any coal tar disinfectant, such as cyllin; this given occasionally will be found useful. Also an occasional dose of a teaspoonful of flowers of sulphur is a good thing.

" W. G. B.," Leighton, asks if splints are termed an unsoundness, and would they prevent a horse getting a Government veterinary certificate; also, is it any use trying to remove them and what is best to do ?

Reply—Splints are an unsoundness if causing or likely to cause lameness. They are not scheduled as an hereditary unsoundness, and the question of rejection or otherwise would lie with the examining officer. As a rule they are reabsorbed as the horse grows older, but may be much reduced in size by rubbing them briskly with a smooth round stick, such as a piece of broom handle, for five minutes or so daily; care must be taken on the second and third days not to injure the skin, which will be very tender.

" A. A.," Farrell's Flat, has a year-old draught colt with a large fluctuating swelling of the hock, with which he was born. He asks would it be advisable to open the swelling or blister it ?

Reply—As the swelling is probably a distended oil sac it would be very inadvisable to open it, neither would one blister do much good; but if it is well plastered with Stockholm tar and wool, repeated in a month or two as it wears off, it is possible the swelling will be reduced.

" W. F.," wants treatment for lice on cow; he sends specimens.

Reply—The lice are the common cattle lice (*Hæmatopinus eurysternus*). A wash every week with plenty of soft soap and soda will keep them in check, and if the cow is smeared with any cheap oil and sulphur (2 per cent.) she will soon be rid of them.

" C. F. J." asks regarding sheep that are all right in the paddock, but when driven 30 chains or so get cramp, shiver, and fall, some never to rise again. Shortly after death green water runs out of mouth and nose. Forty out of 150 fall and three or four die.

Reply—The sheep have contracted a braxy-like disease, and any movement such as described affects their hearts, as the disease generally is more severe when the sheep are conditioning. Constant movement from paddock to paddock is advisable, but must be done slowly. As a preventive a lick of equal parts of flowers of sulphur, Epsom salts, saltpetre, and three parts fresh bonemeal will be of use. Bleeding at the eye vein will often save the affected ones. The paddocks being infected should be limed or sprayed with sulphate of iron, 1lb. to 40galls. of water.

" S. S.," Meadows, asks if ticks injure pigs inwardly.

Reply—The so-called pig tick is a louse, the largest of the tribe, and it is connected with the transmission of diseases like swine fever, trichinosis, intestinal worms. Spraying with Cooper's dip or other disinfectant, followed by a rub over with any cheap oil, such as train oil, in which a little sulphur is mixed, will get rid of them.

" W. P." has a horse whose sheath swells at this time of year, but otherwise the animal is all right. He asks the reason.

Reply—Certain changes occur in the blood in the spring, and sometimes, as in this case, Nature cannot get rid of the waste matter quickly enough, and it is deposited in soft tissues like the sheath. A little alterative medicine, such as 1oz. flowers of sulphur once a day for a week, generally puts matters right.

" F. G. B.," Pinnaroo, asks for treatment of cow that gives slightly bloody milk three weeks after calving, and if the milk is injurious.

Reply—A cow with a tender udder will often give bloody milk without any disease being present. The udder should be very gently handled, and after milking the quarter from which the blood comes should be anointed with a little glycerine and arnica, 1dr. of arnica to 1oz. glycerine. The cow may also have with advantage 10 drops of vet. tr. arnica in a little water or bran twice a day for a week. Probably the milk is not more injurious than a black pudding, but, like the latter, should be well cooked before use.

" H. H. D.," Proper Bay, asks for remedy for yacca poison, the cows being paralysed. He also asks if the milk is good for use.

Reply—Prevention is better than cure, and cows should be kept off young yacca. As treatment, sulphate of iron, 2drs. ; nux vomica, 2drs. ; flowers of sulphur, ½oz. ; brown sugar, 1oz., given twice daily in a quart of beer or milk, will effect an improvement. The powder may be given in the food when an animal is getting bran and chaff. It is not advisable to use the milk either for human beings or animals ; if it is used it should be boiled for 15 minutes.

" H. W. T.," Maitland, wants a remedy for an old-standing case of scouring in a cow.

Reply—Chronic scouring in a cow is a symptom of many diseases, two of which are highly contagious, namely, tuberculosis and Johne's disease, so that the Chief Inspector of Stock should be advised. Internal parasites also produce the complaint, and in any case slaughter would be the best course to adopt, taking care to bury or burn the carcass.

"G. B.," Snowtown, had a mare heavy in foal that swells about the hock and knee joints, and asks if it is advisable to do anything, if so, what ?

Reply—The swellings are probably only lymphatic, such as often occur during the later months of pregnancy, and as a rule no treatment beyond laxative food is necessary. One or two ounces of Epsom salts in the drinking water daily for a few days may help.

"F.N.," Murbko, has a mare which went stiff on her front legs a few days after foaling.

Reply—The mare has had an attack of founder, or laminitis, and probably has by this time recovered; if not, she should have an ounce of Epsom salts in her drinking water three times a day for a few days.

Coorabie Branch. "A.B." inquires why a number of mares running together, several carrying twin foals, should foal one and retain the other, finally pining away and dying. This followed a case of slipping foal in which the mare eventually died.

Reply—The history of this outbreak is very suggestive of an outbreak of contagious abortion, the germ of which is taken into the system by the mouth or during service. It would be well to send the particulars to the Chief Inspector of Stock, who would, no doubt, instruct an officer to investigate the matter locally.

The same Branch states that a mare has foaled a very large first foal, has no milk, and will have nothing to do with the foal. A day or two after foaling she goes lame in front. They ask is it advisable to breed from her again ?

Reply—The lameness is probably laminitis, which often follows difficult foaling, and would be the cause of want of milk. A foal digests cow's milk if a good pinch of sugar of milk is added to each pint; but under present circumstances it is doubtful if it would pay to hand-rear it. Probably the mare would breed all right, but as it is possible she would be a poor milker, the advice not to use her is sound.

Roberts and Verran Branch. "A.B." inquires why horses turned into a paddock of real good green feed (wheat and oats) go stiff in front and soon recover.

Reply—Any change of feed causes alteration in the power of digestion, and this reacts upon the blood supply of the feet, so that the stiffness is really a mild attack of founder or laminitis. As recovery ensues no treatment is necessary. Probably if they were bled before being turned on to the field the trouble would not occur.

"T.M." has a 4-year-old colt with hard swelling on its left shoulder. He asks for treatment.

Reply—This is probably a fibrous tumor grown around a gland under the skin; the pain on working is due to pressure. The best treatment is to cut it out by making a slit along its hinder edge, and freeing from its attachments with the fingers, cut the fibrous root, and treating it afterwards with tincture of iodine, painting under as well as over the skin.

" R. A.," Gilles Plains, asks if white paint put on the inside of a water trough will harm cattle drinking the water.

Reply—Yes ; it is calculated to give them lead poisoning, bringing on severe diarrhœa and, later, paralysis.

" A. B. H.," Mount Caspar, Port Lincoln, has a young mare with capped hock. He asks for treatment.

Reply—As the capped hock has been in existence for about three months the best thing will be to foment well with hot water twice a day, and every morning rub in a little oleate of mercury, 10 per cent.—a bit about the size of a bean.

HORTICULTURE.

(Replies by Mr. G. QUINN, Horticultural Expert.)

" Interested " wishes to know the best method of storing apples other than the freezing stores.

Reply.—The best method outside of the freezing stores is to provide a room in which the temperature may be fairly well controlled. This is usually most readily obtained by partly excavating underground and covering the structure which is built therein with a thick roofing of thatch underneath a rainproof roof. The apples should not be exposed to conditions which will cause them to wilt, and usually keep better if piled in fairly deep masses, say, 1ft. deep. If the air becomes too dry at any time the floor may be sprinkled lightly with water ; and, although ventilation is desirable, it should not be encouraged during the dry and draughty parts of the day. When packing the apples into the store, the smaller fruits and those known to be the longest keepers should be placed on the bottom of the stacks ; and it is most important that no unsound or damaged specimens be included.

" H. C. M.," Tungkillo asks—(1) When and with what compound should apple and pear trees be sprayed against codlin moth, and what quantities are used ? (2) Is the bluestone and lime mixture, which is sprayed upon apricot trees to check scab on the fruits, likely to injure the trees ? Is tobacco wash more suitable ? (3) Is it too late to spray peach trees against curl leaf ?

Reply.—The best time to begin spraying apple and pear trees against codlin moth is just when the blossoms have fallen. The remedy used is arsenate of lead, at the rate of about 1lb. to about 20galls. of water. This is procurable in jars of various capacity, and costs about 1s. per pound, from ironmongers and seedsmen. The bluestone and lime compound, known as Bordeaux mixture, is quite safe to use for preventing the scab and shothole fungus on apricot trees if it be made carefully, and freshly-burnt lime used.

The first sprayings are given as the blossoms unfold, and the second when the fruits have reached the size of a grape berry. If properly made, you need not fear injury to the trees. Tobacco wash is useful to kill aphides on peach or other trees, but is utterly useless as preventive of fungus diseases such as the apricot scab and shothole. It is quite useless to spray peach trees for the prevention of the curl leaf fungus after the tips of the leaf shoots emerge from the winter buds.

"Oranges" wishes to know— (1) Average number of cases of oranges that should be given by seven-year-old trees in very good soil, such as that in the valley of the Torrens ? (2) Also average number on good soil such as that on Adelaide Plains ? (3) At what age should such trees be in full bearing ? (4) What is about the cost of planting an orangery, trees 20ft. apart or 110 to the acre ? (5) What should be the yearly cost of cultivation ?

Reply.— (1) Well grown seven-year-old orange trees in alluvial soil should average from two to three cases per tree according to the sort, Navel varieties yielding a lesser quantity. (2) From one to two cases might be expected as an average return from similar trees under the conditions named, but the longevity of the trees under such conditions cannot be guaranteed. (3) The trees should be in full bearing at from 12 to 15 years, according to treatment. (4) The cost of planting per acre is probably from £10 10s. to £15, according to the variety and the ease of preparation of the soil. Navel oranges will cost about £2 10s. per acre more than ordinary types. (5) The actual tillage of the soil should not cost more than 50s. per acre ; but this does not include irrigation, manuring, pruning, and harvesting the crop and destruction of pests. These combined might easily amount to £20 per acre.

"Gardener" wishes to know, as he is about to start an orange nursery— (1) If he should plant the seeds in the place he intends to grow them, or must he transplant the seedlings ? (2) Do the seeds require any special treatment ? (3) How long will it take before they are ready for grafting ? (4) How long, from the time they are grafted will it be before they are ready for sale ?

Reply.— The freshly removed orange seeds are sown in a specially prepared bed usually sunken about 3in. below the surface, and a border of boards put around about 1ft. high. A screen of calico is usually used as a cover over these beds. The seeds are sown about 1in. apart, broadcast, and covered about 1in. deep with loose compost. The surface of the bed must be level, and water is best applied with a watering-can having a fine rose. The cover is kept on until germination takes place, and is then only used to keep off excessive rain, sunheat, or frost ; and during mild days it is not used. The seeds are sown in the springtime, and the young seedlings set out in the nursery bed about one year later. A proportion of them will be ready for budding in the same summer or early autumn, but the tops are not cut off to start the buds into growth until the following spring. Some of the most advanced in growth will be ready to transplant into the orchard the following autumn, say, 30 months from sowing the seeds; but the majority are not ready until the next springtime, which means three years from the sowing of the seeds.

POULTRY.

(Replies by Mr. D. F. LAURIE, Poultry Expert.)

As a rule correspondents writing for advice on poultry ailments forward very little information, and it is therefore impossible to diagnose some of the cases. The following should be noted or mentioned when writing:—*Vermin.*—If poultry ticks, red mites, feather lice are present. *Housing.*—Describe the houses, yards, &c. *Feeding.*—Give full particulars and also state the quality of the food. *Water Supply*, also receptacles for same. *Symptoms.*—Give fully the symptoms as they appear to you; then describe the condition of the bird, whether fat or thin. Describe the nature and color of the droppings. Examine the vent and see if feathers are matted with excrement, or if other abnormal conditions are present. Examine the eyes and state if normal or inflamed. Look in the mouth and on the tongue round opening of windpipe and report if any ulcers or masses of cheesy-yellow appearance are to be seen. Any other conditions which are not normal.

"G. T.," Geranium, reports scabs or warts on head and eye; fowls mope about.

Reply.—This trouble is generally known as chicken pox, is infectious, but seldom causes great mortality. Isolate all affected birds. Bathe the parts in warm vinegar and water, equal parts, dry with a soft cloth, then apply carbolised glycerine (one part pure carbolic, 15 parts glycerine). Use Epsom salts in the drinking water—a packet to each 20 adult fowls.

"E. N.," Sevenhills, writes—I have lost, now and then, a hen from the following disease or, rather, symptoms:—They go about without any energy in them, will not eat or drink, and their comb turns quite pale—this last mentioned symptom is the most conspicuous. Otherwise they look right enough; eyes quite clear, no matter issuing from nostrils.

Reply.—The symptoms, as described, indicate the presence of internal parasites, *i.e.*, round worms, probably of the species *Heterakis*. Numerous cases have been reported this year, and at one period the trouble was in the nature of an epidemic. Treatment is as follows:—Fast the birds for 24 hours and give water to drink but no food. Obtain from a chemist the following powder:—Santonine, one part; ground areca nut, seven parts—by weight. For the flock—For each 20 adult birds add to dry bran and pollard a heaped teaspoonful of the powder and mix thoroughly; then moisten the whole to a crumbly mass. Use enough bran and pollard to give the birds a short feed only. They may be fed as usual in, say, one hour, after the above. For single birds—Seven (7) grains of the powder mixed with pollard or grease to make a pill. Unfortunately the world's supply of santonine is in few hands, and the price has increased very heavily during recent years. This worm powder has stood the test of time, and I am still advising its use in preference to other vermicides, despite its price.

"W. S. H.," Yarcowie, asks particulars for building a house to accommodate 200 fowls, and remarks that he has been told that high perches are injurious.

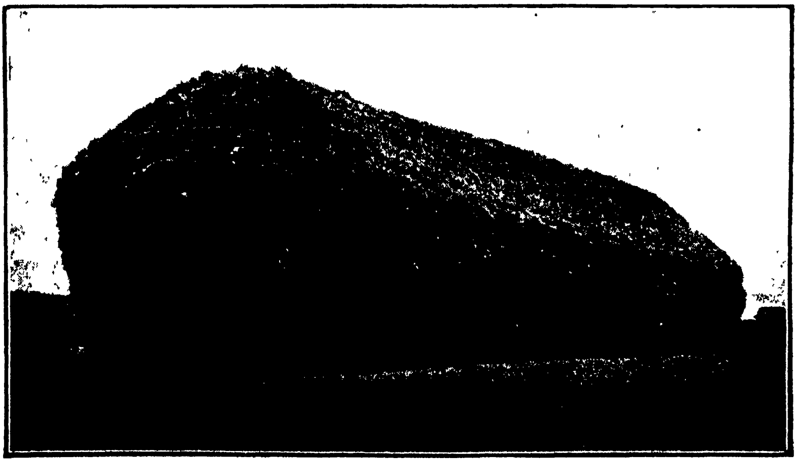
Reply.—A house 20ft. long by 15ft. wide, 8ft. high in front and 6ft. at the back will provide roosting accommodation for 200 fowls ; but must be just twice as long if to be used as a confined scratching-shed house. Use sawn gum or jarrah for the posts—corner posts 3in. x 3in., others 3in. x 2in. The roof, back, and ends must be of corrugated iron. For the roof use two sheets each 8ft., this will allow a 6in. lap in the middle and an overhang at the back. The front should have a galvanized iron windbreak extending 2ft. above ground level. The rest of the front should be enclosed with wire netting and have a door 3ft. wide. Seven perches, 3in. x 2in. jarrah, the top corners rounded off, will provide sufficient roosting accommodation, but must be placed on one level—about 30in. above the ground and about 1ft. 3in. apart. This house should stand in a fox-proof enclosure. If made large enough the breeding yards, cockerel pens, and chicken-rearing yards and houses could also be built in this fox-proof enclosure.

"B. C.," Mallala, writes asking how to prepare an Andalusian cockerel for show as regards food.

Reply.—Without discussing the question of poultry shows and their bearing upon the commercial side of the industry, I must point out that I have no time to advise on matters such as preparing birds for shows. In commercial poultry keeping the results I am endeavoring to promote are good financial returns. In this State there is little profit in showing birds beyond the pleasure of winning a prize. It may be definitely stated that only sound food in proper quantity should be given to any birds, and the use of any special forcing foods or nostrums is to be deprecated. The shading and special housing necessary for show birds creates artificial conditions as opposed to commercial usages.

"T. K.," Pyap, writes detailing his experiences in incubation and asking information as to why fully-matured chickens die before hatching and why others are crippled.

Reply.—The following are contributory to want of success :—(1) Faulty construction of machine—even in the best makes an occasional machine is unsatisfactory. (2) Incorrect thermometer. Very often the mercury column in the thermometer breaks and an apparently insignificant part of the mercury escapes to the top of the tube, where it is unnoticed because the diameter of the tube there is expanded. In consequence the thermometer may be registering several degrees less heat than is really the true temperature. (3) Breeding stock in poor condition, or not suitably housed and fed. (4) Eggs too stale. The best results are obtained from eggs not more than a week old; better still if about four days old. (5) Insufficient airing. The eggs should not be turned for the first three days, and it is better not to open the machine. After the third day the eggs should be turned twice daily and allowed to become just cool. The duration of the cooling process may be extended as the process of incubation proceeds. (6) *Moisture.*—Hot air machines, owing to the difference in atmospheric tension, supply their own moisture during normal conditions. It frequently happens that during dry spells, especially in winter, there is a minimum of moisture in the atmosphere, and consequently a shortage in the egg chamber. When the moisture content of the air is too low the moisture of the egg dries out too quickly. The egg shell is chiefly carbonate of lime. The chicken embryo gives off carbon dioxide which, uniting with the moisture evaporated through the pores of the egg shell, attacks the carbonate of lime and leaves only the organic portion. This may be seen by comparing the shell of a fresh egg with that from which a chicken has hatched. Too rapid evaporation of the moisture, therefore, affects this question. Then, again, there is from 47 per cent. to 51 per cent. of water in the yolk, and from 80 per cent. to 86 per cent. in the white. The solids (mineral fats, &c.) are held in chemical combination with the water, and any undue drying out must have a prejudicial effect upon the chick. The normal drying out process, or evaporation, increases the size of the air sac where the air is first directly breathed into the lungs of the chicken before the shell is fractured. In hot air machines use sponges when dry, and in tank machines keep the water trays in all the time.



Haystack, Turretfield.

SOME ECTO-PARASITES OF POULTRY.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

(*Continued from page* 152.)

The *Menopons—Ricinidæ* or *Mallophaga*.

Neumann says, "The menopons (*Menopon*, Nitsch) generally have the head like the two preceding genera (*Trinotons* and *Colpocephales*), but the orbital sinus is absent or very shallow at the part occupied by the eye; and also that where the antennæ are fixed the latter are always short and indistinct. Living on birds of all kinds except the coursers, Piaget has, on two occasions, found them on mammals—one of them, *M. extraneum*, on the guinea pig."

This louse is extremely active and smooth to the touch, and is the species which moves quickly on the fowl and equally so upon the hand, arms, &c., of persons handling infested birds. These are the most numerous of all parasites in this State. Lives on all parts of the bird's body; is active and constantly on the move; is pellivorous, *i.e.*, lives on epidermic productions (scurf, particles of feather, &c.). They may be considered, not as true parasites, but as commensals; although when in numbers they undoubtedly irritate the skin and set up cachetic conditions ending in death. Some male birds and others do not dust themselves freely and the unchecked vermin soon swarm. Large masses, numbering thousands of eggs (nits), mat the feathers, particularly in the region of the vent. It is always advisable to examine the poultry stock, especially the males, as if infested there will be few fertile eggs. Infested birds soon lose weight and become skeletons; this is due to irritation, &c. Ordinary good insect powders freely shaken among the feathers will result in these parasites being destroyed or so affected that they will drop from the birds. The application of kerosine one part and olive oil three parts is effective, but subsequent contact with dust gives the oiled feathers a dirty appearance. Any good dip—kerosine emulsion, 10 per cent.; formalin, 2 per cent.; or coal tar by-products, 2 per cent. to 5 per cent.—will destroy both parasites and eggs.

Menopon Pallidum, Nitsch.

Neumann says, "The head is slightly angular in front and somewhat crescent-shaped, the temples being bent downwards; the latter are shorter and rounded, with four bristles and some hairs ; there is no appendage to the second article of the antennæ. The thorax is longer than the head in the female ; they are equal in size in the male. The legs are strong and hairy. The abdomen is an elongated oval in the female, narrower and longer in the male, with a single series of bristles on each segment. The general tint is a dirty-yellow, the spots on the abdomen being a bright fawn color. The female is 1·7mm. long and the male 1·8mm.

LUCERNE LEAF SPOT DISEASE.

By T. G. B. Osborn, M.Sc., Professor of Botany and Vegetable Pathology, Adelaide University.

The disease known as the leaf spot of lucerne is generally distributed in all countries where lucerne (*Medicago sativa*) is grown. It is recorded from New South Wales* and Victoria, and in December last specimens were collected from the department's farm at Turretfield. Although in most cases the disease does not appear to cause much damage in South Australia, the importance of the crop it infects is so great that a short account of it may be generally useful.

APPEARANCE.

As in most fungus diseases the infection of the plant is not obvious until a late stage in the course of the disease. The instances in which the actual diseased tissue of a plant can be cured are, for practical purposes, negligible. The treatment of plant diseases in the present state of our knowledge must be preventive rather than curative. It therefore behoves all growers to watch for the earliest signs of an outbreak, to check that, and so to save the remainder of the crop and to give the succeeding crops a better chance of escaping infection.

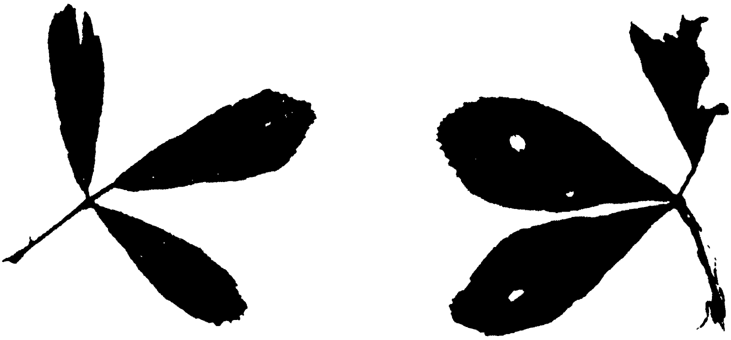

FIG. 1. Photograph of two leaves infected with leaf spot disease. The photographs show the numerous brown areas (see Fig 4). x 2.

In the case of lucerne leaf spot, brown patches appear usually on the lower leaves of the plant (Fig. 1). The individual spot is hardly as large as a pin's head, but there may be so many on the leaf that it appears brownish. The infected leaves turn yellow, and are often shed in such numbers that in cases of severe attacks the plants are almost defoliated. The result is that the value of the crop is reduced, since the hay has a larger percentage of stems. The total yield of the lucerne plot is also decreased, since the vitality of the plants is lowered by the loss of the leaves. An attack of leaf spot is usually noticeable on the first growth of the lucerne plants in early summer. In many cases after the first cut, especially if this has been made before many of the infected leaves have fallen, the disease is not very noticeable. In the United States of America the greatest damage is stated to occur in hot, dry seasons.

---

*Dep. Agric., N.S.W., Farmer's Bull., No. 37, Oct., 1910.

PARASITE.

The fungus causing the disease is known as *Pseudopeziza medicaginis* (Lib.) Sacc. The spores of the fungus germinate upon the leaf surface, and the fungus threads (*hyphæ*) enter the tissue, which they kill within a restricted area—the brown spot. The majority of the spots are on the upper surface of the leaf, though they are not infrequent upon the lower. Occasional pustules are to be found upon the stems, in which position they are usually elliptical. It is probable that each spot is the result of a separate infection, as the vegetative body of the fungus (*mycelium*) is limited to the brown areas and does not appear to ramify throughout the leaf. The reproductive organs are developed from a mass of fungus tissue that is formed just below the outermost layer or the epidermis of the leaf (Fig. 2). These consist of numerous little sacs (*asci*), each containing eight spores (Fig. 3). Standing erect between the *asci* are other fungus threads that do not produce spores. When the spores are formed, the leaf surface above the pustule is ruptured (Fig. 4) and the *asci* are exposed. The thin walls of these are soon broken, and the spores

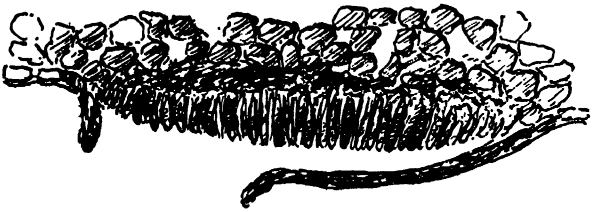

FIG. 2. Cross section of a portion of a lucerne leaf, showing the fructification of the leaf spot fungus breaking through the epidermis, exposing the spore sacs (*asci*). The leaf cells around are dead and discolored. Magnified.

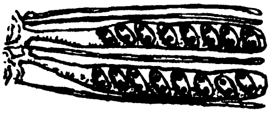

FIG. 3. Two *asci*, each containing eight spores. Highly magnified.

are thus freed. They are then either blown on to other leaves or splashed upon them in drops of water.

CONTROL.

The most practical treatment of the disease is frequent cutting. If the hay is removed as soon as possible from the ground the number of dead leaves left behind will be comparatively small. Thus most of the spores will be removed, and the new growth will be relatively free from infection. This was found to be the case on the Department's farm at Turretfield. If, in spite of the treatment, the disease gets the upper hand, it has been recommended that the crop should be cut and the hay allowed to become thoroughly dry, when it should be burned as it lies over the plot. The area might even have a covering of straw placed over it as well as the hay, so as to secure a good burn.

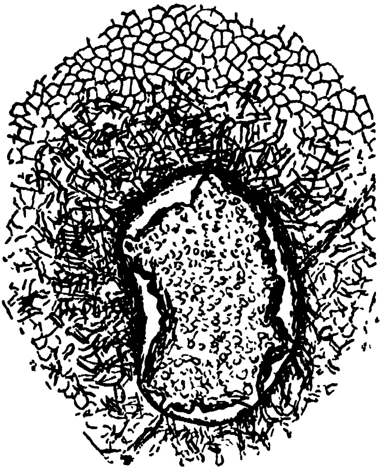

FIG. 4. Surface view of a spot, showing the fructification breaking through the epidermis of the leaf. The *hyphæ* of the fungus can be seen amongst the cells around the fructification. Magnified.

Leaf spot disease is stated to occur in regions where lucerne has not been grown before. The explanation that has been offered is that the spores may be conveyed to the place in the soil used to inoculate the ground with nodule bacteria, or that they may have come with the seed.

A very similar leaf spot disease of clover is produced by *Pseudopeziza trifolii* (Fckl), but it is not known whether infection will occur from clover, &c., to lucerne.

DISEASES OF FARM ANIMALS.

TREATMENT OF WOUNDS.

By C. A. Loxton, G.M.V.C., Government Veterinary Surgeon.

A wound may be defined as an injury to any part of the body caused by violence and resulting in a division of the soft parts. Wounds vary considerably in their gravity upon their extent, situation, and upon the structures injured, extensive flesh wounds often healing readily, while apparently insignificant wounds, such as punctured wounds of joints, often lead to permanent injury—anchylosis, or stiffening of the joint. Those most commonly met with are classed as incised, punctured, lacerated, and contused wounds.

Incised Wounds.

These are clean cuts made with a sharp body such as a knife, the tissues being evenly divided without any loss of substance. As a rule they bleed freely, and where the wound is across a muscle it has a tendency to gape widely. Incised wounds when properly treated usually heal readily, as there is no loss of tissue to make up in the process.

Punctured Wounds.

Punctured wounds are those produced by sharp, penetrating objects, such as stakes, nails, stable forks, &c. Wounds of the feet from treading on nails are of very frequent occurrence, and require special treatment. (*See* p. 847, vol. XVI.) With deep punctured wounds it is difficult to provide for drainage, and the discharges have a tendency to burrow in the tissues. The orifice of the wound being usually quite small, foreign bodies may remain a long time in the wound without being suspected.

Punctured wounds may be regarded as the most dangerous of all, and are most liable of all wounds to be followed by tetanus.

Lacerated Wounds.

Lacerated wounds result when the tissues are torn rather than cut. Barbed wire injuries come under this heading. They do not bleed so freely nor heal so readily as incised wounds, the tearing of the blood vessels preventing bleeding, and the injury to the tissues retarding healing.

CONTUSED WOUNDS.

Contused wounds are caused by blows from blunt objects, falls, &c. In addition to the wound there is bruising of the tissue. If the injury is severe it may lead to sloughing (mortification) of the bruised parts.

HEALING OF WOUNDS.

The manner in which a wound heals depends upon its nature. Where incised wounds are absolutely clean and the cut surfaces are brought close together, there may be direct joining of the cut surfaces and healing in a few days. In the domestic animals conditions are not favorable to this form of healing, and the more common process to take place is healing by granulation, a growth of new tissue taking place and gradually filling up the wound. After a time the new tissue contracts and a permanent cicatrix (scar) results. If two granulating surfaces are brought together and maintained in that position, union will take place much more rapidly than if the wound is allowed to fill up from the bottom.

Healing under a scab takes place when the fluids oozing from the wound dry on its surface and form a protective covering, under which the process of repair takes place.

TREATMENT OF WOUNDS.

The conditions favorable to the rapid healing of wounds are as follow :—Arrest of bleeding. Absolute cleanliness. The edges of the wound to be brought together and maintained in that position. The injured part to be kept in a state of rest.

The first point to be attended to is to stop the bleeding if it is at all serious. This may be accomplished by means of torsion ligature pressure, or by the application of cold ; other means, such as the hot iron, the application of styptics such as perchloride of iron being sometimes used. In cases of severe bleeding from wounds of the limbs a tourniquet may be applied by tying a cord round the leg loosely and then passing a stick through and twisting it until it is tight enough to stop the circulation. This is only a temporary measure until the blood vessel can be secured by other means. Torsion consists in twisting the blood vessel by means of forceps, and is the usual way of stopping bleeding from small vessels. Large vessels should be secured by means of a ligature, by grasping the end of the vessel with a pair of forceps, passing a piece of silk thread or other ligature material round the vessel, and tying it securely. When it is impossible to reach the bleeding vessel, it may be necessary to include a mass of tissue in the ligature. Where other means are not available, a bleeding vessel may be secured by passing a thread under it with a suture needle and tying the two ends. An easy means of stopping bleeding is by pressure, applied by placing a pad of wool over the wound and bandaging it firmly in position. The application of cold water is useful only for checking capillary bleeding, and even then its action is not certain.

Absolute Cleanliness.—This refers not only to the wound itself, but to everything used in connection with it, and includes the hands of the attendant, instruments, needles, silk, &c., which should all be disinfected before use. After the hemorrhage has ceased, and before the edges of the wound are brought together, an examination should be made for any foreign material, dirt, grit, &c., which should be removed, and the wound thoroughly cleansed with a disinfectant dressing. This may be a weak solution of carbolic acid, lysol, cyllin, or other antiseptic.

The edges of the wound are brought together by means of sutures (stitches), pins, plasters, or bandages. This applies more particularly to incised wounds, contused and punctured wounds not being suitable for such treatment. Where stitches are inserted they may be continued from end to end of the wound (continuous), or separate stitches (interrupted) may be used. The latter are most useful, and are made by passing the needle carrying the thread through the opposing lips of the wound, drawing the ends together and tying them firmly in a reef knot towards one side of the wound. After tying, the ends of the threads are cut off short and the knots should lie on one side and not on the wound. Occasionally pins are used by passing them through the lips of the wound and carrying a thread round the ends of the pin in the form of a figure eight. Plasters have a very limited use in the treatment of wounds of animals, and are very little used. Bandages are useful in the case of wounds of the limbs, especially where it is desirable to check the movement of the part, in such cases as punctured wounds of joints (open joint).

As long as the process of healing is going on satisfactorily, the wound requires only cleansing and dressing with antiseptic lotion. Dry antiseptic powders, such as zinc oxide, boracic acid, &c., are also useful in drying up discharges, and are particularly useful in the case of open wounds. Should a wound become inflamed and painful, it must be carefully examined, and if necessary the stitches cut so as to allow efficient disinfection and the escape of discharges. It is advisable to clip the hair from the edges of all wounds to facilitate dressing.

Wounds healing by granulation (proud flesh) should not be checked by the use of caustic preparations like sulphate of copper (bluestone), unless it is excessive in amount. The application of dry antiseptic powders will usually be sufficient, but some wounds, such as those of the lower parts of the limbs, often have a tendency to excessive granulation, and may be covered with a dry dressing and a bandage applied. If this is not sufficient the mass of granulation tissue may be removed with the knife and a pad of cotton wool bandaged over it if the bleeding is severe.

Where wounds fail to heal, and continue discharging in spite of antiseptic treatment, the probability of a foreign body in the wound must be thought of and an examination should be made. It must be noted, however, that great harm may be done in the case of wounds in the immediate vicinity of joints by injudicious probing.

CONSTITUTIONAL TREATMENT.

Constitutional treatment includes attention to the state of the bowels, cooling and easily-digested food, and good surroundings, and should be observed in the treatment of all except minor injuries.

NOTE.—The next article will deal with wounds requiring special treatment.

Wheat Stacks, Port Wakefield.

SPRAYING TESTS AGAINST POTATO BLIGHT.

(*Phytophthora infestans, D.B.*)

By GEORGE QUINN, Horticultural Instructor.

Since this disease appeared in South Australia and attacked the potato crops with such sudden virulence about four years ago, this department has made several attempts to demonstrate the protective value of copper compounds used as sprays upon the growing crops. In the *Journal of Agriculture* for October, 1912, the results of a series carried out in the Mount Gambier district were given, and following upon their inconclusive character another lot was planned in the South-East for the summer of 1912-13. In the meantime, however, at the request of the Campbelltown Branch of the Market Gardeners' and Fruitgrowers' Association, it was decided to arrange for a demonstration in that district, where the potatoes, owing to the mildness of the climate, are grown during the winter season. Mr. Edward Naughton, of Paradise Park, kindly placed a small field at the disposal of the association, and, assisted by the officers of the department, carried out the spraying with considerable skill and enthusiasm.

The plot of ground consisted of about one acre in area, containing 40 rows of plants of New Zealand Pink Eye. They were planted on June 28th, 1912, with good even seed, and the sprayed plots were dug on October 31st, just four months later. Those unsprayed were dug a week afterwards. The rows which were planted north and south were divided into six sections—No. 1 on the western exposed border containing eight rows was sprayed with Burgundy mixture three times, of a strength of 8lbs bluestone, 14lbs. washing soda, to 40galls. of water; No. 2, containing four rows, remained unsprayed as a check; No. 3 was sprayed with a Burgundy mixture of half the above strength, viz., 4-7-40; No. 4, also containing eight rows, was dressed with a Bordeaux spray made of 8lbs. bluestone, 8lbs. quicklime, in 40galls. of water; No. 5, containing four rows, was also kept as an unsprayed check; whilst No. 6, made up of eight rows, was sprayed with Bordeaux mixture of half the strength given to No. 4, viz., 4-4-40. In each case three sprayings were applied. Owing to the rows being set closer together than such widths as the Doncaster horse-power outfit was made to bestride, the gearing had to be discarded and a handle fitted to the pump, so that the spraying was done by handpower. Notwithstanding this, a good cloud of spray was maintained at the rate of 80galls. to the acre.

As previously remarked, the plots were in an exposed position, and after the first spraying—which was applied on the evening of a windy day—the foliage of the plants in the sprayed plots assumed a rusty appearance, of which they never were afterwards free. Although the presence of Irish blight could be detected in these test plots and adjoining fields, it never developed the virulence of an epidemic, and Mr. Naughton failed to record any diseased tubers. This, I believe, is to be attributed to the drying cold winds which invariably followed each fall of rain during the growing period.

In forwarding the tabulated results given below, Mr. Naughton, to whom I am much indebted in connection with this trial, tersely remarked, "As the unsprayed rows took a week longer to mature, the yield from them should be much greater than from the sprayed portion."

Results of Spraying Potatoes against Irish Blight at Mr. E. Naughton's, Paradise Park, 1912.

No. of Plot.	No. of Rows.	Sprayed Three Times with—	Yield of Large Potatoes.			Yield of Small Potatoes.		
			C.	Q.	L.	C.	Q.	L.
1	8	8.14.40 Burgundy	15	1	0	1	1	0
2	4	Unsprayed	8	0	0	0	2	11
3	8	4.7.40 Burgundy	15	2	14	1	1	20
4	8	8.8.40 Bordeaux	16	1	0	1	1	13
5	4	Unsprayed	9	2	0	0	2	0
6	8	4.4.40 Bordeaux	17	3	0	1	1	15

Summary.

No. of Rows.		Yield of Large Potatoes.			Yield of Small Potatoes.		
		C.	Q.	L.	C.	Q.	L.
16	Sprayed with Burgundy	30	3	4	2	2	20
16	Sprayed with Bordeaux	34	0	0	3	1	0
8	Unsprayed	17	2	0	1	0	11

Compared with yields from the unsprayed check rows these figures indicate the negligible gain of 6lbs. in favor of the Bordeaux sprayed plots, and a deficiency of 3cwts. 2qrs. 26lbs. in those sprayed with Burgundy. These results are somewhat difficult to reconcile, but for the fact previously mentioned that the Burgundy plots were apparently injured at the first spraying, either by the wind or the action of the spray following upon the battered stems and foliage.

Results of Mount Gambier Spraying Tests in Season 1912-13.

These were carried out by the Inspector of Orchards for the South-East (Mr. R. Fowler) in careful detail.

As mentioned in the appended report, they are contradictory and inconclusive. Whilst it is very fortunate for the potato-growers of the State that the Irish blight should persistently absent itself from localities where trials are being carried out, yet it is impossible to foretell the nature of the season—in so far as its suitability to the propagation of the disease is concerned—when the first sprayings are given.

Under these circumstances, remedial treatment of this character always partakes more or less of the element of a gamble against possibilities.

In reviewing the history of this disease in climates possessing a dry atmosphere anyway approaching our own, it is very problematical whether, in the long run of years, it will pay to spray potatoes against Irish blight if the crops be grown during the summer months.

REPORT BY INSPECTOR R. FOWLER ON TESTS AT MOUNT GAMBIER.

As in the previous test carried out last season, four plots were chosen, though this time only half an acre instead of one acre in extent, owing to the difficulty of getting suitable plots large enough planted with the same variety of seed.

The plots were again all late-grown potatoes, and were grown by the following growers, Messrs. D. McGillivray, Buchanan Bros., F. Webster, and W. Higgs, and were situated in different parts of the district, that of Mr. McGillivray's being on a block of the recently subdivided Moorak Estate.

The spraying was carried out under fairly favorable weather conditions, though the ground was rather too dry, and in several plots being of a very snuffy nature the wheels of the machine raised such a cloud of dust that the plants were smothered, the dust sticking to the damp leaves. The growing period right through was a very dry one, so there was very slight chance of Irish blight developing in the tops, and I could never find any trace of it in the foliage.

The Doncaster machine worked fairly well, and the improvements effected since it was used in this district last season greatly added to its efficiency.

I visited the plots several times during the season, but only in Mr. McGillivray's was there any marked difference in the foliage between the sprayed and unsprayed ; and in this plot it was very marked, the sprayed plants retaining their green color and growing much stronger and longer than the unsprayed. When the potatoes were dug, however, the results were not so noticeable, the yields being rather poor on account of the very dry season.

Messrs. Buchanan Bros.'s plots were at one time looking very healthy and vigorous, and were an even lot of plants, but soon after the third spraying a very severe frost occurred, and this cut the plots unevenly, so that the figures from this test are of little value, as the plots least damaged by the frost gave the best results. Mr. Webster's plots were unfortunately rather stunted plants, and for some reason never made any satisfactory growth. No. 1 plot was right alongside one of the main roads of the district, and caught a considerable amount of dust. This appears to have had a marked effect on the crop from this plot. The same remark applies to Plot No. 1 in Messrs. Buchanan's. Mr. Higgs' plots were very late grown, and only received their first spraying when the others were done the second time. The plants in these plots grew very luxuriantly, as they caught the rain just at the right time. These were only sprayed twice, as it was so late in the season and there was some difficulty in getting the work done. I did not at any time during the growing period notice any traces of Irish blight in this field, but on being dug I found that blight had developed in the tubers to a slight extent. I am, however, inclined to think, from the fact that in nearly every instance the disease attacked the tubers at the stem end, that the development was under ground from the seed tuber, and not from the foliage above; so that if this surmise be correct, spraying would not be of much use. There was no indication of the foliage being cut down, and the disease appeared slightly in the tubers right through the whole field.

I have to again thank the growers concerned for the assistance given in carrying out the work and for placing their fields at my disposal, and must express my disappointment that the results are not more satisfactory to them from a financial point of view ; but in this, as in the previous test, the main object of the experiment was negatived by the fact that owing to unfavorable climatic conditions no Irish blight fungus developed in the potato haulms. From the point of view of general benefit from the copper sprays, the results this time are not so satisfactory as in the last test, when from all the sprayed plots the extra returns more than paid for the cost of the spraying.

The figures 1.1¾.5 or 10 Burgundy mean 1lb. bluestone, 1¾lbs. washing soda to 5galls. or 10galls. of water; and similarly figures 1.1.5 or 10 Bordeaux mean 1lb. bluestone, 1lb. quicklime in 5galls. or 10galls. of water, as the case may be.

The following are the details of the tests :—

Mr. D. McGillivray's Plot, Dug in June—Sprayed three times, December 18th, 1912 ; *January 9th,* 1913 ; *February 6th,* 1913.

Plot			Large. Bags.	Small. Bags.
No. 1.	14 rows	—Sprayed three times with 1·1¾·5 Burgundy returned ..	29	2
" 2	"	Unsprayed, as check plot	24	3
" 3	"	Sprayed three times with 1.1¾.10 Brgndy. mix. returned	30	3
" 4	"	Unsprayed	24	3
" 5	"	Sprayed three times with 1.1.5 Bordeaux mix. returned	27	3
" 6	"	Unsprayed	23	3
" 7	"	Sprayed three times with 1.1.10 Bordeaux mix. returned	21	3
" 8	"	Unsprayed	17	3

	Large.	Small.	Total.
Totals from four sprayed plots, 2 acres	107	11	118
Totals from four unsprayed plots, 2 acres	88	12	100
	19	-1	18

Apparent gain 18 bags, approx. 1 ton 5cwts.

Messrs. Buchanan Bros.' Plot, Dug in June—Sprayed three times, December 19th, 1912 ; *January* 11*th,* 1913 ; *February* 5*th,* 1913.

Plot			Large. Bags.	Small. Bags.
No. 1.	16 rows	—Sprayed three times with 1.1¾.5 Brgndy. mix. returned	16	11
" 2	"	Unsprayed	25	12
" 3	"	Sprayed three times with 1.1¾.10 Brgndy. mix. returned	32	11
" 4	"	Unsprayed	39	9
" 5	"	Sprayed three times with 1.1.5 Bordeaux mix. returned	37	9
" 6	"	Unsprayed	41	7
" 7	"	Sprayed three times with 1.1.10 Bordeaux mix. returned	43	9
" 8	"	Unsprayed	42	8

	Large.	Small.	Total.
Totals from four sprayed plots, 2 acres	128	40	168
Totals from four unsprayed plots, 2 acres	157	36	193
	- 29	4	25

Apparent loss, approx. difference 25 bags, 1 ton 11cwts.

Mr. F. Webster's Plot, Dug end of May—Sprayed three times, December 31*st* ; *January* 7*th,* 1913 ; *February* 8*th,* 1913 (40*galls. each time.*)

Plot			Large. Bags.	Small. Bags.
No. 1.	14 rows	—Sprayed three times with 1.1¾.5 Brgndy. mix. returned	11	4
" 2	"	Unsprayed	18	4
" 3	"	Sprayed three times with 1.1¾.10 Brgndy. mix. returned	16	4
" 4	"	Unsprayed	12	4
" 5	"	Sprayed three times with 1.1.5 Bordeaux mix. returned	15	4
" 6	"	Unsprayed	11	4
" 7	"	Sprayed three times with 1.1.10 Bordeaux mix. returned	15	4
" 8	"	Unsprayed	13	4

	Large.	Small.	Total.
Totals from four sprayed plots, 2 acres	57	16	73
Totals from four unsprayed plots, 2 acres	54	16	70
	3	—	3

Apparent gain three bags, approx. 4cwts.

Mr. W. Higgs' Plot, Dug in July—Sprayed twice, January 8*th,* 1913 ; *February* 13*th,* 1913.

Plot			Large. Bags.	Small. Bags.
No. 1.	14 rows	—Sprayed twice with 1.1¾.5 Burgundy mix. returned ..	51	10
" 2	"	Unsprayed	49	12
" 3	"	Sprayed twice with 1.1¾.5 Burgundy mix. returned ..	48	12
" 4	"	Unsprayed	47	11
" 5	"	Sprayed twice with 1.1.5 Bordeaux mixture returned .	49	10
" 6	"	Unsprayed	47	15
" 7	"	Sprayed twice with 1.1.10 Bordeaux mixture returned.	54	12
" 8	"	Unsprayed	56	15

	Large.	Small.
Total from four sprayed plots, 2 acres	202	44
Total from four unsprayed plots, 2 acres	199	53
	3	-9

Apparent loss 6 bags, approx. 8cwts.

It is noticeable in this field that there is a much larger percentage of small and waste in the unsprayed than in the sprayed. The reason for this, perhaps, is that the diseased tubers would be put in with the small. Mr. Higgs had the small and waste from sprayed and unsprayed put into separate heaps, and also large from both put into separate stacks, so that I may get some further information from these plots when these are picked over. I visited the stacks recently, but the disease does not appear to be making any headway just now.

Cost of Spraying.—This worked out much the same as last season. It took 80galls. to the acre plots in 1911-12, and it took 40galls. to the half-acre plots in 1912-13. This is as much as the machine will put out. I do not consider it enough, but think it would more effectually cover the foliage if 100galls. could be put on to the acre. Allowing 80galls. to the acre the cost for materials would be approximately -16lbs. bluestone at 3½d., 4s. 8d.; 28lbs. soda at 8s. cwt., 2s.—total for 1.1¾.5 Burgundy, 6s. 8d.; 16lbs. bluestone at 3½d., 4s. 8d.; 16lbs. lime at 2s. bag, 6d.—total for 1.1.5 Bordeaux, 5s. 2d. For weaker solution half the above amounts.

Time Taken.—With the machine in good working order it took about two hours to do the two acres, actual working time, with mixtures all ready to go into the sprayer.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on September 3rd, there being present Mr. G. R. Laffer (Chairman), Professor Perkins, Col. Rowell, Messrs. C. J. Valentine, C. J. Tuckwell, J. Miller, A. M. Dawkins, and G. G. Nicholls (Secretary).

Sheep-dipping.—The following resolution from the Strathalbyn Branch was tabled:—"That the Government be asked to make it compulsory for all public saleyards where sheep are sold to have a suitable dip placed therein." The Secretary explained that the resolution was the outcome of a movement which had been initiated by the Naracoorte Branch, with a view to make sheep-dipping compulsory throughout the State. The matter was referred to the Chief Inspector of Stock for a report.

Experimental Farm Wanted.—The Green Patch Branch submitted a resolution "That a properly equipped experimental farm on Eyre's Peninsula is necessary, because it is impossible for individual farmers to carry out the experimental and research work involved in solving the many problems to be met. The solution may mean the difference between profitable and unprofitable agricultural occupation of several million acres of land now being opened on Eyre's Peninsula. We therefore ask the Advisory Board to bring our views on this matter before the Minister, and do all else possible for the early establishment of a properly equipped and managed experimental farm on Eyre's Peninsula." The Secretary mentioned that the Minister had recently stated that it was not improbable that an experimental farm would be established in the Minnipa Hill district at some future date. It was decided to refer the matter to the Director of Agriculture.

Constitution of Board.—The Wilkawatt Branch desired that when the next vacancy occurred on the Board a representative of the Pinnaroo district should be elected to fill the position. At the instance of Mr. Dawkins it was agreed to inform the Branch that the members were chosen, not to represent districts, but industries.

Mount Remarkable.—The Mount Remarkable Branch wrote asking the Board to request the Government to resume the forest leases on Mount Remarkable proper, and to bring to account the persons responsible for wilfully setting fire to the timber thereon. While admitting that the timber should not be ruthlessly destroyed, Mr. Tuckwell stated that owing to the roughness of the country it was practically impossible to use it. Matter referred to the Minister for report from the Conservator of Forests.

Outward Wharfage. A copy of the letter bearing on the question of the abolition of outward wharfage was brought under the notice of the Board by the President of the Woolbuyers' Association (Mr. J. W. McGregor). The Chairman desired an expression of opinion from the members whether the communication ought to be considered by the Board, as it seemed to some extent to deal with a political matter. While several members of the Board felt that the importance of the matter to the producers and manufacturers demanded careful consideration, in view of the political aspect of the question, on the motion of Col. Rowell, it was decided merely to receive the letter and inform Mr. McGregor of the position in which the Board was placed.

New Branches.—Approval was given to the formation of the following new Branches, viz.:—Myponga—Messrs. G. Hunt, C. Sampson, M. McGuinness, H. Pengilley, F. Pengilley, L. Boothby, H. Sampson, H. Oldfield, G. Maslin, K. Stephenson, E. Everard, W. Paul, A. Sinclair, F. Stock, A. Stock, H. Stock, C. Forrest, J. Muller, F. Muller, A. Rowley, A. Hooper. North Bundaleer—Messrs. C. E. Smart, A. E. Wood, T. O'Dea, W. Wilson, R. P. Kelly, C. Annesbury, W. Shadporth, P. E. Kelly, M. Dundon, A.

Burton, W. Pollard, M. Cronin, J. Scriven, G. Lambert, W. Martin, H. Wood, J. Burton.

New Members.—The following gentlemen were admitted as members of the Branches shown, viz.:—Clarendon—W. G. Dowling; Beetaloo Valley—L. Reid; Blackwood—M. Baust, A. K. Ashby, C. A. Davis; Strathalbyn—B. Heijus; Bute—W. Buchanan; Arthurton—F. H. Nicholas, G. Staples; Lyndoch—R. Manning, W. Noble; Mallala—D. Argent, W. H. Temby, W. H. Lindsay; Meningie—W. H. Yates, jun., F. A. Daenke; Yorketown—G. H. Hart, C. Anderson, W. Kirsch; Orroroo—F. W. Churcher; Watervale—G. Holder; Georgetown—J. White, C. Wilkins, M. Hynes; Pine Forest—A. H. Dolling, T. H. Edwards; Claypan Bore—I. Dudley; Wirrabara—M. Mahood, H. Jericho; North Booborowie—T. D. Phillips; Shannon—J. Brewer; Berri—J. W. Pedley, C. Melville; Hartley—A. Stein; Wilkawatt—J. Windfield; Riverton—W. E. Blatchford, J. E. Hannaford, A. Mills, H. Mills; Butler—F. J. Dunstan, J. Owen, Y. M. Unvois, W. A. Sedunary; Roberts and Verran—J. C. McCallum; Mangalo—W. J. Deer, C. M. H. Muller; Coomooroo—W. Barber; Monarto South—B. B. Paech; Borrika—E. R. Miel, J. E. Maycock, G. Miel; Gawler River—E. White, E. H. Mitchell, S. Pederick, W. Roediger; Two Wells—J. W. Hart; Penola—R. Howard; Mount Barker—A. Watson, A. M. Coppin, W. Wibbley, B. Fuller, G. R. Jones, C. Miels, W. Jacobs; Canowie Belt—J. Henschke, H. Coles, A. Brooks, J. O'Mahoney, F. Heinrich; Coonawarra—W. Mudge, C. Skinner; Monteith—C. J. Morris, J. A. Wytken, T. G. Clark; Julia—D. Hombsch, H. Hyde, J. Jaffer; Sutherlands—P. T. Gehling; Lameroo—H. W. Dragomueller, P. Tink; Woodside—G. Sutherland; Mitchell—A. E. Howell, J. Sampson, D. Ness, S. Sinapins, M. McCormick, G. J. Wright, E. C. Jenkins, E. Dyke, J. H. Vigar, G. Jericho; Parilla—C. Foale; Arden Vale and Wyacca—D. W. Stokes; Yadnarie—A. J. Hutchinson, H. Bauers; Nantawarra—J. H. Nicholls.

Life Membership.—The distinction of life membership was conferred upon the following gentlemen, viz.:—Messrs. Hugh Kennedy, Lyndoch; J. Watson, Mount Gambier; W. Head, Port Germein; E. S. Matthews, Angaston; R. Barr, jun., Pine Forest; W. Francis, Appila-Yarrowie; H. Hart, Millicent; A. Wilson, Tatiara; W. R. Whittaker, Port Broughton; F. Lehmann and J. Stanton, Hartley.

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

CURRENT TOPICS.

During September there was much activity among poultry breeders. The bulk of chickens required by the breeders, except perhaps those intended for the laying competition, are hatched during September or October. Numerous reports are to hand, and the general results of hatching and rearing so far seem to be satisfactory. The day-old chicken trade is becoming an important branch of poultry-breeding. Many people have neither time for nor inclination to use incubators, and broody hens are becoming yearly scarcer. In some parts of the world—apart from Egypt—there are co-operative hatcheries. In Australia and New Zealand, as elsewhere, the rule is that various breeders—noted and otherwise—sell day-old chickens, the progeny of their own stock. A few people buy eggs from other breeders, some buy shop eggs. One breeder last season sold close upon 5,000 day-old chickens, and there are numerous breeders who sold varying numbers. This development in the industry must make for great expansion, and, as a rule, improvement. The quality is governed somewhat by the prices charged. Many breeders sell only those chickens which are bred from reliable stock. It is hoped that few, if any, will sell chickens bred from pullets or from inferior stock.

At the Show.

The Royal Agricultural Show is always an event among breeders, and it was pleasing to note the large attendance of fanciers, and also to note the keen interest displayed by the public generally. Space does not permit of a lengthy discussion of the various sections, but among the notable ones I have great hopes of are the three all-round white breeds, viz., White Orpingtons, White Wyandottes, and White Plymouth Rocks.

The White Orpingtons are becoming very popular, and are highly spoken of by the various breeders. The White Wyandotte has always been a favorite of mine, and if bred on proper lines will become an ideal farm fowl. The White Rocks are forging ahead, and time will show their value or otherwise. The absence of feather markings on these three breeds allows more attention being paid to type, size, and egg production. Another breed which made an attractive display was the Rhode Island Red. This breed is very popular in England, and is said to be very hardy and the hens good layers of standard-sized eggs.

In regard to show Leghorns the type of the winners was much more in accord with the true type of the breed. It was also a treat to see such a fine display of turkeys. Turkey-breeding is well worthy of more general attention.

THE DEPARTMENT EXHIBIT.

The departmental exhibit at the show this year differed in some respects from former exhibits. The usual display of poultry foods with explanatory cards was staged, and also many thousands of eggs, showing proper methods of packing and grading. These object lessons may be familiar to show visitors, but there is room among our producers for improvement which may be learned from these exhibits.

Foods.—The average poultry breeder pays scant attention to the value of variety of grain and other foods, nor is he yet alive to the vital importance of unlimited green food of the proper kinds.

The progress of the industry was shown in numerous large photographs of large poultry plants recently erected in the State. These represented only a few of the principal ones designed by the Poultry Expert for various breeders. Those displayed referred to the poultry plants of Messrs. Pope Bros. & Co. and J. Claridge, of Hectorville ; C. J. Chandler, of Sargenfri, East Payneham ; and F. H. Heinrich, of Freeling. I had a chat with Mr. von Rieben, who has recently erected a fine modern plant on a very large scale at Plympton. This I hope to visit before long.

Models.—Models of brooder-house brooders, chicken house and yard, scratching sheds, and farmers' poultry yards attracted so much attention that many people had difficulty in seeing them. This method of instruction evidently meets public approval, and will be extended at future shows. It is intended later on to issue a bulletin describing the various styles of housing and yarding under modern conditions. A number of applications for plans and particulars have been received.

GENERAL PURPOSE POULTRY CLUB.

The newly-formed General Purpose Poultry Club requested my help in the form of a lecture illustrated by fine lantern views depicting the various breeds and varieties to promote which the club has been formed. Thursday night of the show week is a time when most visitors to the show have had enough hard work, and there are various counter attractions ; still, about 160 people attended, and, after hearing the objects of the General Purpose Poultry Club, the numerous breeds were explained and fine slides screened. Mr. A. O. Thomas, of Hindmarsh Square, provided a fine electric lantern, which gave good definitions. He also procured for me a remarkable film shown by a bioscope and depicting the early stages of incubation; it was a wonderfully clear lesson in embryology. The actual process of hatching out and drying were also well shown. This film will be available on future occasions.

VISIT TO PARAFIELD.

During the show week numerous visitors from the country who had to leave the city before Saturday were given permits to inspect the poultry station. On the Saturday morning about 70 ladies and gentlemen journeyed by train and a score or so more went by motor car, trap, &c., to the poultry station. There the works in progress were inspected and the general scheme fully explained. A fusilade of questions on all poultry subjects continued throughout the visit. The laying competition—906 fowls—attracted great attention. The birds were released from their houses that morning for the first time since April 1st. Some, who were much against the idea of confinement, looked surprised when they saw that numbers of the birds had returned to their comfortable houses and were busily scratching. The incubation house, in which all the machines are heated by air gas; the two big brooder houses, each 100ft. long, also gas-heated, were inspected. In the brooder houses there were about 2,000 chickens and in the chicken runs some distance away there were 1,000 odd chickens in all stages of growth. The breeding stock, feed houses, workshop, &c., were all points of interest. Doubtless each year at show time there will be similar gatherings at Parafield, and each year it is hoped good seed (of an educational nature) will be sown among the visitors.

OPERATIONS FOR OCTOBER.

As previously pointed out, all chickens should be hatched not later than October. In a few favored localities, like Mount Barker, the later hatched chickens thrive and grow well, but in the north and in the State generally November and December chickens are not worth rearing. This matter was definitely proved in a series of experiments during several years at the former poultry stations.

Green Food.—The State has been blessed by a most splendid downfall of rain, and it is to be hoped all breeders are planting vigorously for summer and autumn use. Lucerne is, of course, the great fodder for the poultry breeder, but he will also find that sorghum and maize will give a wonderful supply of a fodder much appreciated by poultry. Breeders can hardly give too much green food. The birds can have practically as much as they will eat, and it should be fresh cut and succulent.

Brooders.—Do not overheat the brooders. It is a common mistake. Very little added heat is required, as long as the brooder is cosy and well ventilated.

Vermin.—Look out daily for vermin. Parasites such as ticks, red mites, and lice are responsible for half the losses among poultry. They are as a rule disease carriers. The articles appearing in the *Journal* have been prepared by me with a great amount of hard work to bring before the breeders the importance of this question, and also to illustrate the various sorts of vermin and to explain their habits, &c.

The Chickens must be kept growing without a check. Move them from yard to yard, or, if on free range, move the coops to a different locality. Separate the cockerels from the pullets as soon as the sexes can be distinguished; both thrive the better for this. Give variety in food, and do not overlook the great value of hulled or shelled oats and plenty of green food.

Ducklings for market must be pushed along right from the shell, a check will mean practical loss of profit. Feed liberally, using plenty of green food and also animal food daily; this is essential to success. Keep the ducklings dry and shaded from the hot sun, and see that drinking water is available day and night.

Turkeys.—Most farmers make the mistake of selling their old stock. Turkey hens are not fit to breed from until they are two years old, and it is better to have the gobblers the same age. Breeding from yearling hens is the cause of much of the degeneration which has taken place; this and want of selection.

Eggs.—Collect the eggs daily, and as the weather gets warmer collect twice a day. Provide nests in a cool spot and store the eggs in a cellar. If you have no cellar, one suitable for eggs can soon and cheaply be excavated and made.

Infertile Eggs.—Let me continue to impress the superiority of the infertile egg for market. Dispose of all surplus cockerels and pen the others away from the hens and pullets. Eggs which are fertilised are of little value from a commercial point of view. It is time our South Australian poultry breeders left off selling eggs of doubtful quality. That is the work of a fool or a rogue, surely. If you knowingly sell bad eggs you are scarcely honest. If you do not know by now that a fertile egg soon goes bad you must be foolish. This point has been urged by me for 20 years or more.

Pack properly.—Do not pack dirty-shelled eggs, wash them and dry with a clean cloth. Use sweet chaff and sound boxes. You can buy proper egg cases fitted with fillers and wood wool pads; these minimise breakages and no chaff is required. Bad packing is responsible for great losses, and the only man who bears the loss is the producer. We shall never see the trade as it should be until the system of barter is abolished. The egg trade is one that requires special knowledge, and this the average storekeeper does not possess; at all events he rarely packs his eggs properly.

TABLE BIRDS.

There is a good demand in Adelaide for prime chickens. Fatten the chickens properly before forwarding to market. In a very short time buyers will be operating to fill the Christmas market orders. Have your birds ready early in December. Buyers must have their stocks dressed and packed in the cool rooms before the Christmas market begins. Prices fall and competition eases just about Christmas. Liberal feeding is necessary. Use bran and pollard, or if you have a crusher, use oats and barley and a little maize. Feed on a variety of food and keep the birds quiet and undisturbed. Ducklings are very timid, especially at night. If subjected to nightly disturbance they will lose weight and may even be injured during their frantic rushes. Do not use lime where ducks are. Many cases are on record where much damage has resulted; in some cases deaths have occurred.

Water.—Clean out and scald the drinking vessels. The water supply is often the medium for distributing diseases.

Diseases such as roup (diphtheria) cannot be cured. All sorts of nostrums are sold, and at the best they merely hold the disease in temporary check. In consequence there are periodical outbreaks. Destroy all diseased stock; it is the only sure method. Keep the houses clean and at intervals spray with a good disinfectant. You say it costs money. Just so. If there were no such drawbacks poultry-breeding would be the most profitable occupation on earth. The more skilfully a man houses and feeds good stock and keeps down disease the more money he makes. This is the key. Prevention is better than cure. When disease breaks out it is too late.

Ostrich Farm, Port Augusta.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1913-14.

[Started April 1st, 1913, to terminate March 31st, 1914.]

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

HEALTH.

The birds are in good health and their general appearance is very satisfactory. One pen, however, are all confirmed feather-eaters. On arrival at the competition, on March 31st, the wings of these birds appeared as if picked in parts, and no feathers grew subsequently. The denuded areas have increased, and some brown feathers also appeared. Various remedies have been tried, including a liberal application of aloes ointment. These birds are unsightly.

DEATHS.

Eight deaths occurred, viz., five cannibalism, two found dead, one waster. Owing to cannibalism one pen ceased to compete, as the owner could not forward the necessary replacements. This trouble must be stamped out by breeders—such stock is worthless.

BROODINESS.

During the month the following hens became broody :—Nineteen Black Orpingtons, 4 Buff Orpingtons, 4 Silver Wyandottes, 3 White Wyandottes, 4 Langshans, 2 Dorkings, 3 White Leghorns ; total 39.

EGG PRODUCTION.

The yield continues satisfactorily, and the general averages are well maintained. The 906 birds laid 19,469 eggs ; average per pen 21·48 eggs. *Comparison of Pen Averages*, 1911-12, 1912-13. — 1911-12—134 pens. 473·6 per pen to September 30th. 1912-13—151 pens, 519·0 per pen to September 30th. This shows an increase per pen of 45·6 eggs. The birds were confined in their pens from April 1st until Saturday, September 13th, when the yards were completed and the birds released on the occasion of the first annual visit of farmers and others. The appearance of the birds when released was excellent. A large number of the birds only remained in the yards a few minutes, and then returned to their houses. They were not particularly anxious for liberty.

VISITORS.

One hundred and fifty visitors inspected the Poultry Station during the month. Many of the visitors came for the purpose of noting the construction of houses, &c., and to gain other information. The convenient situation of this Poultry Station will considerably extend its educational value as an experiment and demonstration station.

WEATHER.

Moderate conditions prevailed during the month. The total rain precipitation amounted to 2·60 inches, which was very beneficial to the various growing fodder crops, all of which are looking well, and promising ample provision of green food in future.

D. F. LAURIE, Poultry Expert and Lecturer.

GET RID OF THE FLY.

A DEADLY PERIL.

It is only within recent years that the treachery of flies has been completely proved; hence the ignorance of the general public on this point is not surprising. But now, writes *The American Agriculturist*, that we know that flies do carry these diseases from place to place, it behoves us to fight them as we would a deadly serpent. Recent experiments of the Bussey Institute, the Harvard Medical School, and the Massachusetts State Board of Health have shown conclusively that flies, particularly the stable fly, is the carrier of the much-dreaded virus of infantile paralysis. Some time ago Professor Theobald Smith showed that Texas fever of cattle is transmitted through ticks, and the Government is spending thousands of dollars to meet the difficulty. Following directly on that discovery came the enlightenment that the virus of malaria and yellow fever are transmitted by certain insects, and that of the sleeping sickness of Africa by the tsetse fly. As a result of this work Uncle Sam cleared first Cuba and then the canal zone of the epidemics of yellow fever and the scourge of malaria, which hitherto made living so dangerous for white men in the tropics.

In the infantile paralysis experiments Professor Rosenau and his associates of the Harvard Medical School first infected monkeys with the paralysis germs. They were then allowed to be bitten by the stable fly. After a necessary interval these flies were allowed to bite other monkeys, with the result that the animals exhibited all the symptoms of the disease in six cases out of 12, establishing the fact that the disease can be carried by these insects. The experiment was repeated and confirmed by Drs. Anderson and Frost, of the public health and marine hospital service at Washington; hence the proof is complete that flies carry the virus which has kept the medical profession guessing and parents in constant fear in recent years.

The bacilli of tuberculosis are easily disseminated by the fly, because it feeds on sputum, and because the tubercle bacilli may pass alive through the digestive tract and appear in fly excreta, commonly known as fly specks. Dr. Lord found these germs alive in the excreta of flies fed with sputum 15 days after they had been passed.

Who, either at home or in some public restaurant, has not been compelled to fight for his food with the myriads of house flies that swarm about? The wonder is where they all came from. Investigation would probably show one or more of three causes operating—One, neglected garbage; two, some stable with accumulating manure ; or three, a dump near by. At the seashore other species of fly than the house fly find the dead fish thrown on shore an excellent breeding-ground.

To thoroughly grasp the best means of fighting them, it is well to recall their repulsive life cycle. Flies lay their eggs upon horse or cow dung, decaying vegetables, meat, cheese, dead animals, and human excreta. The larvæ emerge from the egg and feed on the mass on which they were deposited. After a variable number of days they shut themselves into their skin, which forms a hard case around them, and in it they are known as pupæ. There they undergo the marvellous transformation into the winged insect.

Characteristics of Stable Fly.

The stable fly, which is especially dangerous to human beings, is much like the ordinary house fly, to which it is closely related, and for which it is frequently mistaken on account of size, somewhat similar coloration, and common occurrence near human habitations. However, the Harvard alumni bulletin points out that they differ in some respects of habit, structure, and distribution.

The adult stable fly feeds exclusively on blood, biting various animals, and less commonly human beings. Naturally, they are more common in the country, where there are more animals, although it is difficult to find any place of any size where, under ordinary conditions, the fly does not occur. The stable fly does not enter houses so commonly as the ordinary house fly, but is inclined to remain in the open and sunny places, except when attracted elsewhere to feed. It appears early in the spring, and becomes more abundant in midsummer, and stays later in the fall than the house fly. Its breeding-places are much the same as with the house fly.

How to Fight the Peril.

The great question is how to control the fly peril. The campaign must be one for general cleanliness and neatness, as well as a campaign against a troublesome pest. Ordinary fly traps and sticky fly paper are used to good advantage with the house fly, but are practically useless with the stable fly. For the latter, the most important control measure now known is to attack its breeding-places. Any methods which will do away with or exclude manure piles, decaying plant or animal life, from flies is to be recommended. Direct removal in the summer of all animal waste is important to the farmer, not only for the safety of his family, but because it is a good principle of agriculture.

Extreme care should be exercised in the protection of closets. In this day of improved hydraulic rams, gas engines, &c., bathrooms are within the reach of many farmers who thought them a luxury half a dozen years ago.

A thorough campaign of education should be followed. Let the schools, the women's clubs, the bureaus, and civic organizations take the lead. Spread abroad the facts that flies are deadly enemies of mankind, and encourage all possible means of reducing their number. Encourage local boards of health to assert their powers and duties in the matter; co-operate with the State Board of Health. See to it that all foodstuffs are properly screened, and teach the importance of absolute cleanliness at the barn as well as in the house. Eternal vigilance is the price of freedom from filth and flies.

Public-spirited individuals, the council or other progressive body, may well institute fly-swatting contests. Encourage children, and grown-ups as well, to kill off these traitors by the thousands. It is surprising what a little well-organised effort will accomplish in this connection. One can do much alone, but this is a campaign which is both a public nuisance and a public menace. Watch out for your own premises, and if your neighbors are inclined to be negligent, study means of bringing them into line.

Killing by Means of Poison.

Millions of flies can be poisoned, and Professor R. P. Smith, of North Carolina, makes a good suggestion in this connection. He says, "Formalin is a very successful poison for flies. I have used it extensively with excellent results. I take two tablespoons of formalin to one pint of equal parts milk and water. In this proportion the mixture seems to attract the flies much better than when using sweetened water. Expose the mixture in shallow plates. A piece of bread in the middle of the plate furnishes more space for the flies to alight and serves to attract a greater number of them. I first used this poison in a milk room, where the flies were very abundent, and killed over 5,000 of them in less than 24 hours. Another experiment was tried in a large calf barn, where flies were numerous. I exposed six ordinary-sized plates of the formalin mixture, and killed 40,000 (four quarts) flies between 12 o'clock noon and 8 o'clock the next morning. I could cite many cases where the formalin mixture has been used in unscreened kitchens and dining-rooms, and resulted in killing practically all the flies. A good place to use it is on the front and back piazzas, where flies are frequently numerous and waiting to enter whenever the doors are opened."

THE AGRICULTURAL BUREAU.

TWENTY-FIFTH ANNUAL CONGRESS.

SILVER JUBILEE CELEBRATION.

The Twenty-fifth Annual Congress of the Agricultural Bureau was inaugurated on the evening of Monday, September 8th, by a banquet in the Brookman Hall, School of Mines and Industries, held to commemorate the 25th anniversary of the foundation of the organisation.

The function was attended by about 320 members of the Bureau, representing practically every district in the State, and a number of other prominent citizens. The Chairman of the Advisory Board of Agriculture (Mr. G. R. Laffer) presided, and he was supported by His Excellency the Governor, the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), Colonel Rowell, Professor Perkins (Principal of Roseworthy College), Messrs. A. M. Dawkins, J. Miller, C. E. Birks, C. J. Valentine, G. Jeffrey, W. G. Auld, C. J. Tuckwell, and T. H. Williams (members of the Advisory Board), the Commissioner of Public Works (Sir Richard Butler), the Victorian Director of Agriculture (Dr. Cameron), Professor Osborn (Professor of Botany and Vegetable Pathology), the Government Geologist (Mr. L. Keith Ward, B.A., B.E.), the Registrar of the School of Mines and Industries (Mr. L. Laybourne Smith). Colonel Castine, and officers of the Agricultural Department.

The toast of " The King " having been honored, the Chairman read several apologies received for non-attendance, including one from the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), who was absent through ill health.

THE GOVERNOR.

The Chairman gave " His Excellency the Governor," whose presence at that celebration of the 25th anniversary of the foundation of the Agricultural Bureau they regarded as an honor, and appreciated fully. During the time His Excellency had been in the State as representative of His Majesty he had embraced every opportunity of travelling about the State and making personal acquaintance with its resources and possibilities. (Applause.) Probably there was no other gentleman present who could more quickly sum up the possibilities of their land than His Excellency, who had come into contact with large numbers of people of all classes, and had not taken greater interest in any of them than in the men on the land. Particularly was that so in regard to those who had gone towards the outskirts of civilisation to subdue the wilderness and place it under cultivation. His Excellency realised that those pioneers were not only benefiting themselves and the State, but were helping to solve one of the greatest problems of Australia the peopling of the unoccupied areas of the Commonwealth. They all realised that if Australia was to become great and prosperous the first essential was not building towns and cities, but the development of the natural resources. It was not by living in congested cities that progress was helped, but by going out upon the land and developing its resources in agriculture, horticulture, and viticulture. Not only had His Excellency moved among the producers at their shows and other places, but had delivered speeches which it had been a pleasure to hear and read, and a prominent feature of which had been their Imperialistic tone. They realised with regret that that would be the last time His Excellency would attend a similar gathering, and he (the speaker) was certain that among his pleasant recollections of South Australia would be the sincere well wishes of the producers. (Applause.)

HIS EXCELLENCY'S REPLY.

His Excellency thanked the Chairman sincerely for the kind words with which he had proposed the toast and those present for their cordial reception of it. He heartily congratulated the Bureau upon the attainment of its silver jubilee, which they were commemorating that night. The Agricultural Bureau might well be proud of the part it had played during the last 25 years in the agricultural history of South Australia; the Bureau was not only a splendid educational institution, it was also an admirable social movement, as well as a disciplinary organisation for the formulation of a common agricultural policy. (Applause.) He very highly appreciated the opportunity afforded him at that and kindred gatherings, not only of getting into touch and sympathy with the agriculturists and pastoralists of the State, but also of learning at first hand from those best qualified to inform him of their difficulties, their anxieties, and their requirements, as well as the development of their wellbeing, their comfort, and their success. The meeting together of the farmers from all parts of the State gave opportunities for comparison of the results of their labors, as well as for the interchange of friendly social intercourse between those who, for the greater part of the year, were widely separated, and was of immense benefit, not only to themselves, but also to the agricultural industries of the State. Addressing the Chamber of Manufactures recently, he had said that the purchasing power of the community was mainly based upon the success of the agriculturists and pastoralists in their production and export of primary commodities, and that both manufacturers and agriculturists should take warning from the barometer when the mercury steadily flowed to the top of the glass and persistently remained there. The annual value of wool, of wheat, and of wine, was in the first instance a measure of the wellbeing of the pastoralist, the agriculturist, and the vigneron. But it was far more than that. It was a kind of barometer which predicted the measure of prosperity or otherwise which was about to visit all the employers of labor in the State, and especially the railways, hotels, motor car builders, tramways, and, because it largely affected the State revenue, even the power of the Government itself to provide employment for those workmen who depend for their subsistence upon daily wages. A large proportion of Government expenditure was justly based upon construction of railways, by means of which the cultivation of wheat-bearing areas and closer settlement might be extended and connected with the seaports of South Australia and the markets of the world.

THE RAILWAYS AND PRIMARY INDUSTRIES.

The railways, under the able management of the Commissioner (Mr. Moncrieff), had nobly responded to the demands imposed upon them, and this year had not only paid off every penny of the interest owing on the large sums originally spent in construction and maintenance and accumulated during the bad years of drought, but had also produced a net revenue for the year of £828,691, leaving a surplus of £262,101 as a credit balance. The aggregation of this sum was largely the result of pastoral and agricultural prosperity, of the efficient transport over the railway lines, of the enormous amounts of stock and agricultural commodities which the farmers of South Australia had produced, and to the conveyance of minerals from Broken Hill to Port Pirie. They should recognise the fundamental economic fact that it was principally the primary productive industries which had enabled the railways to achieve their financial success, and had also added to the wealth, paid the wages, and maintained the high standard of comfort which now existed in South Australia. The year 1912, like its predecessor, was exceptionally dry, September and October having been distinctly unfavorable. The late sown crops, however, had been wonderfully revived by the exceptionally fine general rains which fell during November.

SOUND DEVELOPMENT.

Taking all the circumstances into consideration, the returns for 1912-13 showed a remarkable example of sound agricultural development, and when considered in relation to the flourishing condition of the secondary industries, the extension of public and commercial utilities, the creation of ports and harbors, the construction of railways, tramways, roads, and bridges, the erection of towns, hospitals and churches, schools and colleges, the record of South Australia during the comparatively short period of 76 years would be hard to excel. But the development of the country was continuing and proceeding by leaps and bounds; the achievements of the past would be more than equalled by those of the future. In order to supply the insistent demand for land new country had to be opened up. This was first found in Pinnaroo. The success of the venture was immediate and striking. In five years after the opening of the railway. 1,580,000bush. of wheat and 15,600 tons of hay had been reaped from 145,000 acres, and that on soil previously thought unfit for cereal cropping. Fruit to the value of £130,000 was being annually returned from 5,000 acres at Renmark on the River Murray, and *The Lancet* had declared that the finest oranges which ever came to England came from there. (Applause). Railways aggregating 500 miles, and designed to serve approximately 8,000,000 acres, were being constructed on Eyre Peninsula and south-east of the Murray in the Brown's Well district. It was safe to predict that the 8,000,000 acres to be served by new railways would be ultimately taken up and successfully farmed. A continuance of prosperity and expansion for South Australian agricultural industries was therefore practically assured.

THE IMMEDIATE OUTLOOK.

The experience of South Australia in the past had been marked by the recurrence of dry seasons, during which the farmers had suffered severely by the loss of their live stock and the diminution of their crops. Although they still hoped for the best, there were signs that the present year might bring a drought of exceptional severity, which must heavily weigh upon the resources and endurance of the farmer, and through him exercise a far-reaching effect, not only upon every industry and upon every trade and business, but also upon every branch of the public service which depended for its upkeep upon the revenue of the State.

There were, however, certain gleams of sunshine to lighten the gloom of the apparently impending ill-fortune. In the first place the country was in a far more prosperous condition and better prepared to encounter difficulties than ever before. The wheat-bearing areas of new country on Eyre Peninsula and the Brown's Well and Pinnaroo districts, which he had already alluded to, appeared to be less affected by the dry conditions of the present season than the plains of Adelaide, and it seemed probable that those more distant areas, as well as the West Coast and Yorke Peninsula, would exercise a markedly favorable influence on the total amount of grain to be reaped during the harvest of 1913. The reticulation of the great reservoirs at Beetaloo, Bundaleer, and Barossa, the prosperous condition of the people, evidenced by the flourishing state of the Savings Banks and of the Mutual Provident Society of Australia, which was believed to be doing the largest insurance business in the world, together with the results of the harvests during the last 10 prosperous years were all advantages which this generation had received from its fathers, and which had cast upon it a heavy responsibility. This generation, having certain advantages handed down to it, might yet find itself in the position occupied in bygone days by their fathers, the pioneers, a position which might again require the exercise of the qualities of fortitude and endurance. In such a case who could doubt our farmers would show the same magnanimous spirit in self-sacrifice which their fathers, the pioneers, had before displayed when struggling through hardships and difficulties in order to achieve the prosperity and comfort which they had handed down to the present generation.

RECUPERATIVE AUSTRALIA.

There was, however, another and a brighter outlook—a silver lining to the cloud of gloom—which was to be found in the extraordinary revivifying properties of the Australian soil and climate. (Applause).

In 1828, after two years of drought, Sturt had found the Darling a navigable river, but as salt as the sea. Ten months afterwards, when one good season had intervened, Sturt returned to the Darling and had found a navigable river as before, but of purely fresh water. No matter how much flocks and herds might be reduced during an Australian drought; no matter how bare and scanty the harvest, the effect of one or two good seasons appeared to be always sufficient to restore the numbers of the live stock and to reinstate the fertility of the fields of grain.

Those considerations should ever be borne in mind and help to fortify their minds to bear present loss, in the hope of future prosperity, comfort, and happiness, if not for themselves then certainly for their children. They should remember how in recent years after every drought the advance had always been greater than before, and how much had been achieved in the past in spite of bad seasons, and how much they therefore might expect from the future. (Applause.) He thanked them again for their kind and cordial reception, and offered them his heartiest good wishes for the prosperity and success of the farmers of South Australia and their Agricultural Bureau. (Applause.)

THE MINISTER'S SPEECH.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.) proposed "The Agricultural Bureau." He was pleased to see so great a gathering of agriculturists and members of the Bureau as were present that night. With all present he regretted that it would be the last time His Excellency would be among them. They had reached the high-water mark of the prosperity of the Bureau. (Applause.) He was proud of the work of the Bureau during the last 25 years. Its history had been one of continuous progress. In 1888 there were 10 Branches of the Bureau, nine of which were still existing. To-day it had 160 Branches and a membership of 3,500. In 1889 the average yield per acre under the old system, and before they had solved the problem of successful occupation of the land, was 7·9bush. on a rainfall of 25¼in. In 1912, with a rainfall of a little over 14in., it had increased to 10bush. 34lbs. (Cheers.) One of the factors in that result was the educational value of the Bureau system, and it was upon that phase of the work that he wished to speak that night. They had been learning during the past quarter of a century, and by learning had increased their strength and power.

ROSEWORTHY COLLEGE.

Among the factors which had helped them was the Roseworthy College. The achievements of that institution had been of value not only to this State, but to the whole of the Commonwealth. Some splendid men had passed through the college, and the other States had always been glad to get hold of them. That was a well-deserved compliment to the institution and to South Australia. They were glad to be able to supply the other States with men to administer their departments. Last year, it was noteworthy, the dux of the college had gained higher marks than had ever before been recorded. (Applause.) The students trained at Roseworthy on going out among the farmers had done much to revolutionise the agricultural industry and popularise the Agricultural Bureau system. Not only was the college educational from the standpoint of the students, but also from the experimental standpoint of the farmers. The experiments conducted included rotation of crops, manures for wheats, handling sheep on the Lower North farms, effects of heavy dressings of manures on the feeding value of the herbage, depth of ploughing, and the general treatment of bare fallow, the feeding value of hay cut during various stages of growth, including digestion tests, which he believed were the first of their kind in Australia. (Applause.) The college also dealt with forage crops, irrigation, and experiments, forest trees for domestic growth and fencing, and organic manures for the vineyard and orchard.

KYBYBOLITE.

One of the chief matters which Mr. Colebatch (the Superintendent of Agriculture in the South-East) had to deal with at the Kybybolite Experimental Farm was that of overcoming the surplus of water in the South-East. The subjects specially treated at Kybybolite were cheap and effective drainage, forage crops, grass and clover crops, light and heavy dressings of manure, and permanent experimental fallow plots, hand selection of cereals, and explosives and electricity for clearing. There were demonstration plots in six different parts of the South-East, and last year the Kybybolite Farm had had the most successful year since its establishment.

TURRETFIELD AND BOOBOROWIE.

At Turretfield, which was typical of the greater part of our safe country, they were doing the work they had formerly performed at Parafield. They were experimenting with the object of growing fodder for stock purposes without reducing the area under cultivation for wheat. It was hoped that the result would be that the farmers within the safe districts would be able to increase their wheat yields, and at the same time strengthen the lamb trade. They were also experimenting to ascertain how far horse traction could be superseded by other power. At Booborowie they were doing similar work, and making experiments in regard to manures. They had found that where they had supplied ¾cwt. of superphosphates per acre there had been a yield of 23·6bush. Where they had given 1cwt. there had been a return of 24·2bush. The cost of extra manure at 5s. a hundredweight had been 1s. 3d., and the profit from extra wheat at 3s. 4d. a bushel, deducting the cost of extra manure, had been 9d. an acre. Where 1½cwts. of manure had been used there had been a yield of 27·1bush., the cost of extra manure had been 1s. 9d., and the extra profit 7s. 11d. an acre. (Applause.) They could add to these results the increased fertility of the soil for grass and future crops. Thus they found that by increased manuring they could carry more stock on the land when not using it for crops, and the "blighting-off" theory was, in addition, exploded. Their tests at the same place with various quantities of seed wheat had shown that with Marshall's No. 3, when 40lbs. were sown to the acre the yield was 20·4bush., and where 55lbs. were used the yield was 22·5bush. an acre. The cost of extra seed at 4s. a bushel was 1s., and the value of the increased yield at 3s. 4d., after deducting the cost of extra seed, was 6s. an acre. Besides the recognised Government farms, they had agriculturists throughout the country who were conducting tests under Government supervision. Those were of great assistance to the department.

HORTICULTURE.

Then they had the Horticultural Expert (Mr. Quinn). It was generally recognised among the fruitgrowers that he was a man who knew his work. (Applause.) He was doing valuable service in investigating diseases peculiar to the orchards and finding remedies for them. Included in the work being carried on at the Government orchards was the testing of remedies for diseases, the effect of different manures, methods of pruning, which must, of course, go on for years to be of value, and the testing of different varieties of trees in regard to their ripening seasons and general superiority.

POULTRY.

Another valued officer was Mr. D. F. Laurie, the Poultry Expert, who for many years had fought an uphill fight. The new poultry station at Parafield was not quite complete yet, but arrangements were being made for a visit to it on Saturday next, and he was certain those who cared to make the trip would find it interesting and educational. Thousands of pounds were now being spent each year by private individuals, who had come to realise that poultry breeding was a profitable industry if properly looked after. The value of the poultry products was not less than £700,000 per annum, and the value of the exports to the other States amounted to £150,000 per annum. It augured well for the future of the industry that notwithstanding the increased production the average market value for eggs in 1912-13 showed an advance of 3d. per dozen over the average price for 1904.

DAIRYING.

Then they had the Dairy Expert (Mr. Suter), who had done a great deal to educate the people of this State in that branch of agriculture. South Australia, as they were aware, was not regarded as a dairying State. The farmers in the safe districts of the north found it better as a rule to grow wheat and raise other stock; but as the reclaimed areas on the Murray River came to occupation it was likely that more attention would be given to dairying. Mr. Suter had lectured with much success to school children, who were taught the first principles in the management of dairy stock.

Mr. Jackson, the Wool Expert, who belonged to the School of Mines, was also one of their most valued officers engaged in the education of the rural community. (Applause.)

THE VETERINARY LECTURER.

Recently the Government had appointed as Veterinary Lecturer Mr. Place, who had done much good work. (Applause.) Last year he attended 48 Branches of the Bureau, addressed 145 meetings, and he had travelled 16,000 miles in connection with his work. He had received many letters of thanks and appreciation from farmers and Bureaus respecting Mr. Place's lectures.

THE LAMB TRADE.

He regretted that the lamb export trade had fallen off owing to various influences, including unsatisfactory climatic conditions, during the last two or three years, and emphasized the bright prospects in various parts of the world for frozen meat. He strongly urged the farmers to give to this branch of the industry their closest attention. South Australia was being brought increasingly under the notice of the consumers in the old country, and in that respect Major Norton, the Trade Commissioner, was undoubtedly doing splendid work.

A WELL-ORGANISED DEPARTMENT.

They had probably read in the press that the Agricultural Department was in a state of chaos. If concentration meant chaos, the department was undoubtedly in that condition. If the leading officers working harmoniously together and with the Minister meant chaos, chaos certainly reigned. But he ventured to assert that never before in the history of the department had the officers worked so amicably together, and with the Ministerial head. (Applause.) He had visited many of the district conferences, and had found much pleasure in attending them. It did one good to witness the activity and intelligence displayed by the delegates, especially by the younger men All that showed that the agricultural industry must improve and increase under such conditions. (Applause.)

As a further means of disseminating knowledge, they had *The Journal of Agriculture*, which had a circulation of over 6,500, and contained much information useful to the producer. Coupled with that they must not forget the valuable help the Bureau had received from the two leading daily papers. Practically every agricultural conference in city or country was attended by the special representatives of *The Advertiser* and *The Register*. Two or three members of the Advisory Board always attended the district conferences, which were greatly appreciated. He had found South Australian farmers in every part of Australia except Tasmania, and he had always found them a success on the land. He supposed they were also working successfully in Tasmania.

BRIGHT HOPE FOR THE FUTURE.

He had told them of the activities of several of the branches of the department. The gratifying feature of it all was the existence of that grand institution, the Agricultural Bureau, with its effective organisation which enabled the officers of the department, after they had searched, tested, and proved, to come right into touch with the men on the land and give them what they had to impart. For 25 years that had been going on in some degree, and they had put to the practical test the suggestion of the scientist, and had proved that which was good. The result had been better farming, better and more produce, and greater prosperity to the producer and the State. Therefore, the bright hope for the future was that the Agricultural Bureau might still be the means of helping the men on the land to solve the problems and overcome the difficulties of their calling, rendering them less liable to serious inconvenience in odd seasons which may be unfavorable, and establishing them firmly as a most prosperous class. While they had an institution like the Agricultural Bureau, and a Director of Agriculture like Professor Lowrie, they need not fear for the future welfare of the primary industries of South Australia. (Applause.)

A VICTORIAN TRIBUTE.

Dr. Cameron (Victorian Director of Agriculture) said he was so sensible of the good work which had been done in years past by the South Australian Agricultural Bureau that he deemed it a very great honor indeed to be allowed to participate in the silver jubilee of the Bureau. He desired to thank Mr. Pascoe for having extended to him through the Victorian Minister of Agriculture the invitation to be present that night. No sooner had that invitation been received than his (the speaker's) Minister had directed that it be accepted. He had realised that the visit would undoubtedly prove of benefit to the farmers of Victoria. It was considered throughout the Commonwealth that the South Australian farmers were in the van so far as cereal growing was concerned. They were more successful in that department than any other State in the Commonwealth. Right from the time of the introduction of chemical fertilisers, the drill, fallowing, rotation of crops, and all the other advanced methods of agriculture, the other States had benefited from the pioneering work performed by the South Australian farmers. He believed, from what he had heard and read and from what he personally knew, that though the Agricultural Bureau had not perhaps actually conceived those advances, it had matured each and every one of them to the point of success and adoption in agricultural practices. And, once adopted by the farmers in South Australia, the farmers in other parts of the Commonwealth had quickly followed their lead. He was aware that the South Australian press appreciated the work of the Bureau, and gave the Agricultural Department all help possible. In that connection he desired to correct a slight typographical error. In one of the papers here it had been stated that the Agricultural Bureau of South Australia had become such a success that the other States were envious of it. He thought what was meant was emulous. (Applause.) He wanted them to understand that the feeling in the other States towards the Agricultural Bureau was not so much one of envy as of admiration. It was true that none of the other States had so far been successful in establishing an organisation on exactly the same lines as the South Australian Agricultural Bureau, but they had established kindred organisations. In Victoria, for instance, they had what was known as the Chamber of Agriculture, and the last farmers' convention held at Bairnsdale in connection with that body was attended by 460 farmers. He endorsed all that the Minister of Agriculture had said with regard to the excellence of the Roseworthy Agricultural College, and he wished publicly to acknowledge their indebtendess to South Australia for the reform of the stud horse industry, accomplished by Mr. Colebatch (the manager at Kybybolite), and to express his appreciation of the excellent services now being performed in Victoria by two old graduates in Mr. Richardson and Mr. Wilson. (Applause.) He deeply regretted the absence of Professor Lowrie, but hoped that the Director would soon be restored to good health. (Applause.)

Professor Perkins, in responding to the toast, mentioned that he had been directly associated with the Bureau for 21 years. His official position enabled him to claim first-hand knowledge of the immense value of the organisation as a system of arteries for conveying information of value to the farmers. It stood for all that was progressive in the practice of the rural industries.

Mr. A. M. Dawkins, representing the Northern Districts, also paid a tribute to the educational value of the Bureau.

Mr. E. M. Sage (West Coast District) thought there was no more useful institution in the State so far as the farmers were concerned.

Mr. J. C. Ruwoldt (South-Eastern Districts), who had been connected with the Bureau for 25 years, mentioned that the effect of the institution was an improvement in agricultural practices in the district.

Mr. P. J. Edwards (Eastern Districts) said that the Bureau was of immense value in a new district such as the Pinnaroo, especially as those taking up the land were generally unacquainted with the conditions.

LIFE MEMBERSHIP CERTIFICATES.

His Excellency the Governor then handed certificates of life membership to the following:—Angaston—S. O. Smith, F. Salter, A. Friend, E. S. Matthews; Appila-Yarrowie—W. Francis, J. C. W. Keller; Arden Vale-Wyacca—M. Eckert; Arthurton—T. B. Wicks; Balaklava—P. Anderson; Burra—J. H. Rogers; Carrieton—J. W. Bock; Cherry Gardens—G. Hicks; T. Jacobs, C. Ricks; Clare—J. H. Knappstein; Cradock—P. Gillick; Dawson—C. H. Meyers; Gawler River—T. B. Parker, R. Badcock, H. Roediger; Green Patch—E. M. Sage; Gumeracha—D. Hanna, J. Monfries; Hartley—J. Stanton; Hawker—A. C. Hirsch; Kanmantoo—W. G. Mills; Longwood—W. H. Hughes; Lyndoch—H. Kennedy; Millicent—H. Hart; Minlaton—S. Vanstone, J. McKenzie; Mount Gambier—J. Watson, J. C. Ruwoldt; Mount Pleasant—W. Lyddon; Narridy—H. Nicholls; Penola—H. Ricketts; Pine Forest—R. Barr, jun.; Port Broughton—G. E. Pattingale, W. R. Whittaker; Port Elliot—J. Brown, W. E. Hargreaves; Port Germein—W. Head; Port Pirie—E. J. Hector, T. Johns; Quorn—J. McColl; Renmark—W. H. Waters; Stockport—D. G. Stribling, J. Murray; Watervale—G. Hunter; Whyte-Yarcowie—Hon. T. Pascoe, M.L.C.; Wilmington—W. Slee, A. H. Noll, J. Schuppan, R. G. S. Payne; Wirrabara—P. Lawson; Woodside—C. W. Fowler, A. S. Hughes; Yongala Vale—A. Jamieson, sen.

THE BUSINESS MEETINGS.

Tuesday, September 9th.

MORNING SESSION.

The business sessions of the Congress were commenced at the School of Mines and Industries on Tuesday, September 9th, when Mr. G. R. Laffer (Chairman of the Advisory Board of Agriculture) presided.

During the sittings the following delegates attended:—Amyton—W. Gum; Angaston—F. Salter, S. O. Smith; Appila-Yarrowie—J. H. Bottrill, W. C. Francis; Arden Vale and Wyacca—J. A. Absalom; Arthurton—J. H. Colliver, W. R. Stephenson; Bandon—G. G. White, J. T. Colbert; Beetaloo Valley—J. L. Murphy, P. Curtin; Belalie North—T. Dunstone, D. Fox; Berri—W. F. Clayer, W. R. Lewis; Blackwood—A. W. Magarey; Blyth—A. L. McEwin, O. Eime; Booleroo Centre—W. Whibley, O. E. W. Bruns; Borrika—R. Collins, S. R. Haynes; Burra—J. H. Rogers, E. Finch; Bute—W. Sharman; Butler—G. Parker, R. W. Phillis; Canowie Belt—R. Carter, E. T. Daly;

Carrieton—J. W. Bock, G. Fuller; Clanfield—A. Correll, W. J. Booth Clare—J. H. Knappstein, J. Dux; Clarendon—A. Harper, sen., A. Phelps; Claypan Bore—F. S. Tall; Colton—E. H. Whitehead; Coomandook—W. Ninnis, C. M. Wilkin; Coomooroo—G. B. Lillicrapp, E. Berriman; Coonalpyn—E. E. Williams, A. J. R. Gurner, J. J. Cronin; Coonawarra—J. Skinner; Coorabie—N. M. Roberts; Cradock—M. Neylon; Crystal Brook—H. Billinghurst, B.A., M. P. Pavy; Davenport—J. Holdsworth, A. Bothwell; Dawson—J. Nottle, C. H. Meyers; Elbow Hill—W. T. Cooper; Forster—W. J. Sears, T. Searle; Frances—A. J. Baldock, J. McGillivary; Freeling—A. J. Kuhlmann; Friedrichswalde—F. W. Schutz, G. Grope; Gawler River—W. Rice, B. F. Hillier; Georgetown—M. J. McAuley, S. Eyre; Geranium—W. J. Mitchell, W. Pannell; Gladstone J. Sargent, T. Mutter, R. Lines; Glencoe—A. Dow, G. E. Copping; Goode—V. J. Tonkin; Green Patch—E. M. Sage; Gumeracha—D. Hanna, J. Monfries; Hartley—F. Lehmann, J. Stanton; Hawker—A. C. Hirsch; Ironbank—C. Morgan, R. Coates; Inman Valley—H. J. Dennis, J. W. Crompton; Julia—T. Prior, W. H. Neal; Kadina—J. Malcolm, R. Correll; Kalangadoo—D. W. Tucker, T. Bott; Kanmantoo—J. Downing, W. G. Mills; Keith J. MacIntyre, J. A. Lock; Koppio—W. Jericho, G. B. Gardner; Kybybolite -H. Lacey, C. A. Scholz; Lameroo—E. T. Wray, A. J. A. Koch; Leighton—T. Goodridge, W. Bailey; Longwood- J. R. Coles; Loxton—W. B. Russell; Lyndoch—H. Kennedy, A. Springbett; MacGillivray—A. Sands; Maitland—J. Hill; Mallala—A. E. Temby, J. Nairn; Mangalo—J. H. Cleave, J. W. Deer; Meadows—W. J. Stone, A. L. Ellis; Meningie—T. W. R. Hiscock, F. W. Newson; Millicent—H. F. L. Holzgrefe, H. Day; Monarto South—G. A. Hartmann, C. F. Altmann; Monteith—C. A. Bentley, A. Clark; Moonta—J. Atkinson, W. B. Stacey; Morchard- J. Scriven, W. Reichstein; Morgan—C. A. R. Wohling, J. Pope; Mount Barker—J. Pope; Mount Bryan—A. A. Jefferies; Mount Bryan East J. W. Best, R. Thomas; Mount Gambier—J. E. Watson, J. C. Ruwoldt; Mount Pleasant—H. A. Giles, W. Lyddon; Mount Remarkable—J. McIntosh, N. S. Giles; McNamara Bore—G. H. Perriam; Nantawarra—S. Sleep, R. D. Nicholls; Naracoorte—W. H. Smith, S. H. Schinckel; Narridy—J. Darley, P. Haren; Narrung—S. Bottrill, W. J. L. Thacker; North Booborowie—W. E. Hannaford, A. V. Simpson; Northfield—J. Williams; Orroroo—J. B. McDougall, J. C. Hagger; Parilla—H. G. Johnson, J. H. Dewhurst; Parilla Well—J. W. Johnston, E. H. Leak; Parrakie—F. J. Dayman, M. J. Cooney; Paskeville—J. P. Pontifex, T. H. Price; Penola—D. Adamson, H. Ricketts, sen.; Petina—O. J. Howard; Pine Forest—D. Carman, A. Hewett; Pinnaroo—P. J. Edwards, P. H. Jones; Port Broughton—G. E. Pattingale, W. R. Whittaker; Port Elliot—W. E. Hargreaves, J. Brown, W. Squires; Port Germein—J. Stewart, H. Crittenden; Port Pirie—J. Greig, A. M. Laurie; Quorn—R. Thompson, J. Brewster; Redhill—F. A. Wheaton; Renmark—W. H. Waters, H. S. Taylor; Riverton—J. P. Schultz, E. A. Gray; Roberts and Verran—R. Johnston, F. Masters; Saddleworth—W. Scales; Salisbury

—E. Moss, A. G. Jenkins; Spalding—E. E. Gill; Stockport—J. Murray, D. G. Stribling; Strathalbyn—J. W. C. Fischer, A. Beviss; Sutherlands—A. M. Twartz, jun.; Tarcowie—J. Burgess, A. MARKETING WHEAT.

Mr. S. Trengove (Bute Branch) read a paper on "The Marketing of Wheat" as follows:—

Improvement in the quality of South Australian wheat has for some time remained practically at a standstill, although much advance has been made in the quantity produced per acre. I believe that at one time South Australian wheat was looked upon as being the finest placed upon the world's markets, and, as a consequence, commanded the highest price. The highest price to-day is given for the hard Manitoban wheat; but our wheat is much sought after because of its value for mixing or blending. In fact, we are led to believe that most of our wheat is used for mixing purposes, and on that account we get a better price than that generally obtained by other wheats. We are credibly informed that during the last twenty years South Australia has not improved her wheat at the same rate as many other countries, and consequently it will only be a matter of time and we shall be left behind in the race. Let us see if we cannot find the reason of this apparent apathy among farmers which has led to the present unsatisfactory state of affairs.

A Premium on Carelessness.

The present system of buying wheat, while it has much to commend it, yet contains within itself the germ of all this trouble. Let us take, for example, two farmers delivering wheat to the same buyer. Both samples come up to the all-too-low standard. One sample, however, is well cleaned and of extra good quality and contains only 1 per cent. of dirt, while the other contains 6 per cent. of rubbish and small and inferior grains. Both farmers receive the same price for their wheat. The fact that the second farmer gets rid of 5 per cent. more rubbish than the first pleases him and encourages him in his careless habits. What encouragement does this offer to the first farmer who has brought in a good sample of wheat well cleaned. He realises that his neighbor, with a far inferior sample, has been paid as much per bushel as he. Here we have a type of farmer who, with a little encouragement, would soon improve the standard of wheat grown; who, knowing he has not received payment according to value, becomes careless also, and begins to think that as long as his wheat will pass the buyer that is all he need trouble about. Thus, buying in this way has a downward tendency on both farmers. From the above, it will be seen that the second farmer has delivered in 1,000 bags of wheat 60 bags of dirt and rubbish and inferior grains. Assuming the rubbish to be worth one-third of the value of wheat, and that wheat is worth 10s. per bag, there is £10 to be made up from somewhere. Wheat must be bought and sold on a law of averages. Therefore, we find that the first farmer is actually placing in the pocket of the second farmer a substantial cheque by allowing the poor wheat to be mixed with his good wheat. Accepting the view that wheat containing 1 per cent. dirt is clean wheat, an additional 5 per cent. represents, with wheat at 3s. 4d. per bushel, 2d. per bushel actual loss at the wheat stacks. Follow the wheat in and out of the stack, per train to the seaport, thence to London, extra handling, insurance, and cornsacks, and it is seen that this extra 5 per cent. of dirt has entailed enormous cost without any corresponding good results for the outlay; and all this might have been avoided by the farmer exercising more care.

In going around a district before reaping commences, it is often not a difficult matter to find crops containing 10 per cent., and even 20 per cent., of smut. This wheat when brought into the yard, although smelling very strongly of smut, is placed in the same stack as the good wheat. Against the practice of mixing poor wheat with good, and passing the whole as f.a.q., I raise my protest. If a farmer brings in wheat containing a lot of dirt or badly affected with smut, the agent ought to refuse to take it at top price.

ONE OF THE REASONS.

The merchant who allows his agent to buy wheat irrespective of the quality and condition of the same, and pays top price for all, is not the true friend of the farmer. But when we find, in a little country place producing only, say, 40,000 bags of wheat per year, and six or seven firms with three agents there, some of whom are buying on commission, one of the causes of poor wheat being bought at top price is explained. The agent has a living to make, and well knows that if he refuses to take a sample of wheat at top price every buyer in the yard will be tried until one is found to take it, when, not only does he lose that wheat, but no more will he get from that farmer for the season; and this is by no means an uncommon occurrence.

I have attempted in this paper to point out some of the things which have led to carelessness in placing wheat upon the market. That such carelessness does exist is beyond question. Several very large farmers, to my knowledge, say they never pickled a grain of wheat and yet always obtain top price for their wheat, smutty or not. If our farmers would all use a good seed grader and carefully clean their wheat from every foreign seed, pickle the wheat with a good solution of bluestone as a preventive of smut, and then, when harvesting, use a good open screen to allow as much rubbish as possible to pass into the screening box, a much better sample would be obtained. A higher standard could then be fixed, which would be a step in the right direction, because the world's buyers, seeing a high standard, would be more eager to buy. Not until farmers and merchants take a commomsense view of the matter and work together to place upon the world's market the best sample possible can we hope to have much improvement.

THE DISCUSSION.

Mr. G. B. Gardner (Koppio) considered the writer of the paper had raised an interesting question. The only way he (the speaker) could see of getting over the difficulty was that there should be two standards for wheat. Farmers were docked if their wheat was a trifle below the standard, and therefore they should be paid extra if the grain was above the standard. At present if their wheat went 5lbs. over the standard they would get no more than another man whose wheat only just reached the standard. That was an incentive for farmers not to clean their wheat.

Mr. W. B. Russell (Loxton) considered something should be done to encourage the man who took the trouble to get a good, clean sample. At present there was no inducement to do that, as so long as the wheat passed the standard that was all that was required. There were some farmers who said if their wheat passed the standard they might as well get paid for the dirt in it.

Mr. W. Gum (Amyton) said he had for a number of years advocated that the man who cleaned his wheat properly should get a higher price than the farmer who was careless, but whose wheat just came up to the standard. He had mentioned the matter to wheatbuyers, but they had always said that it would cause a good deal of dissatisfaction in the district if a man who brought in a good sample got a better price than the man who brought in a poor sample. He thought the dissatisfaction would be on the part of the man who brought in the poor sample, and he would soon find that it would pay him to clean his wheat properly. (Applause.) He had seen wheat brought to market with a tremendous amount of rubbish in it, although the grain was of good quality. If farmers made it their business to clean their wheat well they would find they would soon reap the benefit.

Mr. H. Smith (Naracoorte) congratulated the writer of the paper on having introduced the question, which had for a long time been a burning one. While the farmer was at the mercy of a few buyers who combined to fix the price of wheat he would never get the advantage he should for properly cleaning the wheat. What was the good of the farmer cleaning his wheat and bringing in a good sample when he did not get any recompense for the extra trouble he had been put to. Let them consider the difference as regards wool. Wool went into the open market and was bought according to its quality. It therefore paid the woolgrower to grade the wool. Until the farmers combined so that they might dictate to the wheatbuyer instead of the latter dictating to them, they would have to put up with the present state of affairs.

Mr. F. H. Lock (Whyte-Yarcowie) thought many farmers were glad to hear that the standard had been fixed on the low side, but it was absolutely to their disadvantage. One thing certain was that the merchants were "on a good wicket," and likely to remain there until the farmers woke up and demanded a fair deal. If a farmer cleaned his wheat well and brought to market a sample which went 2lbs. or 3lbs. above the average he got no more for his wheat, but if it happened to be ½lb. below the standard he was docked. The merchant bought wheat up to the standard, and also that over the standard, at the standard price, but for anything below the standard he paid less, so that every time he stood to win. The suggestion that there should be two standards had been made, but he did not think much benefit would result from that. In America and other places they did not go in for the standard business at all. The farmers graded their wheat and sold it on its merits. South Australia was one of the few wheat-growing countries that adhered to the bag system, and while they stuck to that there would not be much improvement. The bulk handling of wheat was a question which must be considered. The bulk-handling system had been proved in New South Wales and other places both economical and effective, and why should it not be adopted in South Australia? It was fairly certain that the wheat merchants would not help them to get that system introduced, and the farmers would have to make a move themselves. If they showed that bulk handling would mean a saving in money and labor, the Government would go into the question. He did not say the system could be worked economically in South Australia, but it was one which must be inquired into. The system of bulk handling was wonderfully economical as regards labor and in other ways, and the various Branches should certainly discuss the question, so that some idea of the cost of its introduction might be obtained.

Mr. E. F. Pearce (Whyte-Yarcowie) said the question of marketing wheat was one that had been exercising the minds of the farmers for a long time past. The competition amongst agents was so keen in his district that if an inferior sample was brought in there was no trouble in getting rid of it at the same price as that paid for the best sample offered. He knew that some farmers covered the screens of their harvesters because otherwise they took out too much of the rubbish. He did not say that that was creditable to the farmers, but from the point of view of pounds, shillings, and pence, those who adopted that practice undoubtedly reaped an advantage over the man who cleaned his wheat thoroughly but got no more for it. So far as he could see the adoption of bulk handling offered the most likely solution of the trouble. That system was the best for handling grain which had been devised, and as the railways belonged to the State, and the elevators should belong to the State, the farmers here would not, as a result of bulk handling, be like they were in America--crushed by the railway companies and elevator owners. It was not only a question of getting more for their wheat, it was also a question of saving the enormous loss occasioned year after year through damage to sacks, and other expenses such as agents' salaries, all of which came out of the pockets of the farmers.

Mr. D. W. Tucker (Kalangadoo) said it seemed to him that it would be wise to do away with the standard for wheat altogether ; then the wheat could be sold like wool, on quality, and the man who had the best wheat would get the best price. A lot had been said about the farmers being "got at" by the buyer, but from what they had heard about covering up screens, it appeared that the buyer was also being "got at" by the farmer.

Mr. A. J. Lock (Keith) said the question was one of great importance to farmers. Undoubtedly there was an understanding among the merchants, and it was time that the farmers combined. If wheat was below the standard the farmers were docked, but it all went to England as one standard.

Mr. F. Gasmier (Wilkawatt) urged the necessity of farmers uniting together. At present they had no say whatever in the price of wheat. They had simply to go to the buyer and ask what was being given. The farmers should unite and not sell to the merchants at all, and should not export 1bush. of wheat to England, but should send it all away in the shape of first-class flour. He agreed with the writer of the paper that wheat should be properly cleaned, so that the standard of South Australian wheat might be maintained.

Mr. W. R. Stephenson (Arthurton) took exception to the statement that there had been no improvement in the quality of South Australian wheat during recent years. In a climate like that of this State quality did not altogether depend on cultivation, but very largely on the quantity of moisture. There was a great deal to be said in favor of cleaning the wheat, but, as had been repeatedly pointed out, there was at present no advantage in doing so.

Mr. D. G. Stribling (Stockport) said a great deal had been said in regard to how badly the merchants were treating the farmers, but he did not think the farmers had much to complain about. He thought the merchants treated them very fairly. There was, perhaps, a time when it paid to put dirty wheat on the market, but now, with labor and land so dear, that time had gone by. The farmer from a sense of pride in his calling, if for no other reason, should grow clean wheat, and if he did so he would find he would be very fairly treated by the merchants. The farmers in South Australia to-day were getting as good a price for their wheat as many merchants were getting on the English market.

Mr. G. H. Periam (McNamara Bore) said that the man who started on mallee country had great trouble through the shoots, and found that no machine would clean the wheat properly unless it was put through a grader. Mallee farmers could not afford to go to that trouble. If wheat were marketed in bulk the farmers would have to produce a much better quality than when the grain was put in bags, because the bags hid a lot of impurities mixed with the wheat. He did not think there was much to complain about in regard to the wheatbuyers. The difference in the price given by the merchants here and the price the merchant received in England was very little. If wheat were marketed in bulk the farmers would have to bring in a first-class sample, and they would find they would be docked more than at present. How could they get the barley out? The wheat would have to be passed through special machinery to get the wild oats and barley out.

Mr. A. L. McEwin (Blyth) said there was no place in the world that had made so much improvement in the quality of its wheat as had South Australia. He believed the wheat merchants were men of high integrity. Something had been said about going to the wheat merchants and demanding a better price. Did they realise that the whole of the wheat grown in the Commonwealth would not supply the European market for more than two weeks? Under those circumstances how much control did they have over prices on the European wheat market? He believed they could market their wheat more cheaply by the elevator system, as bags were very expensive. He had paid £350 a year ago for bags alone. They had, however, to consider what position they would be placed in if they had the elevator system. It was a big question, and required a lot of consideration. He did not believe the statement that farmers deliberately allowed dirty wheat to go on the market. If they did they were bigger rogues than he had imagined. (Laughter.)

Mr. J. Brown (Port Elliot) said a farmer who got 10 per cent. or 20 per cent. of smut in his wheat was a dirty farmer. The first essential was to get good seed, and the next thing was to pickle it properly.

Mr. J. Murray (Stockport) said one point had been missed altogether. The careful farmer with a good sample of wheat weighing 67lbs. a bushel did not, when the standard was 60lbs., sell that 67lbs., he only sold 60lbs., and had the remaining 7lbs. in hand. But the man whose wheat did not come up to the standard had to give more than a bushel to make up the weight.

Mr. Smith (Naracoorte) moved—"That the Advisory Board take into consideration the advantage or otherwise of wheat being sold in the open market." The system of selling wheat in the open market would get over the difficulty complained of, and would do away with the agents in the country, the expenses connected with which amounted to quite a penny per bushel. Selling in the open market would also result in the man who produced the best sample getting the top price.

The Chairman pointed out that the Advisory Board was constituted of persons representing various industries, and would not have sufficient time to devote to a question of that kind. Consequently, if the resolution were carried it would be of no effect.

Mr. Smith said he would amend his motion to the effect—"That the question of selling wheat in the open market be referred to the Branches for consideration."

Mr. J. B. Thiele (Sutherlands) seconded the motion.

Mr. N. S. Giles (Mount Remarkable) said the quality of South Australian wheat was not only not improving, but was deteriorating, and it was of no use disguising that fact. If farmers were not careful South Australian wheat would be sold at a discount on the London market. If selling wheat in bulk would remedy the trouble, it should have the support of every farmer in South Australia.

Mr. F. H. Lock (Whyte-Yarcowie) suggested that the question of bulk handling of wheat should also be referred to the Branches.

Mr. G. G. Nicholls (Secretary Advisory Board) said that most of those who had spoken on the subject seemed to desire that action should be taken quickly. If the matter was referred to the Branches it would mean a delay of 12 months, and, in addition, past experience had shown that in all probability a number of the Branches would not even discuss the matter. The Congress was a representative one, and he urged that they should deal with the matter at once.

Mr. Trengove (Bute), in reply, said what he complained about was that in selling sheep he was paid according to the condition in which he brought the sheep to market, but in selling wheat under present conditions the farmer did not get paid according to its value.

Mr. H. Billinghurst (Crystal Brook) moved as an amendment—"That this Congress urge the Government to take such steps as may be necessary to make bulk handling of wheat the ordinary process of marketing in this State."

Mr. N. S. Giles (Mount Remarkable) seconded the amendment.

The amendment was carried by a large majority.

POTATO-GROWING.

Mr. A. A. Sassanowsky (Mount Gambier) contributed the following paper:—

In dealing with this subject I do not set myself up as an expert, but will endeavor to give you some idea as to the way in which potatoes are grown around Mount Gambier, more particularly in the Compton Downs district.

The soil in this particular part is not of a volcanic nature, but is a fairly stiff loam with a good clay subsoil.

As you are, no doubt, quite aware, the soil differs a good deal on every farm, and the system of working the land for one farm may not suit another.

My remarks on potato-growing will mainly refer to the Snowflake variety, and to a medium late planting, say, about the month of October; the ground on which the potatoes are grown being planted about every sixth year after the land has been under grass for two years.

It is a general practice to plough the land two or three months before planting, and in doing this the growers have various ideas as to the depth of ploughing, *i.e.*, whether it should be 2in., or 6in. to 7in. deep.

I am not in favor of just skimming the land, for if this is done, the reploughing, in planting the potatoes, has a tendency to form lumps.

By ploughing to a depth of 6in. or 7in. the ground can be well cultivated before planting. The after-working is better, and there is more chance of retaining moisture in the soil when ploughed deeply.

Our next work is the planting of the crop about the middle of October, and it must be remembered that we get some fairly warm days at this period which have a very marked tendency to dry the land. Our object is to retain the moisture, and the only way to do this is to harrow the land ploughed each day twice over (reverse ways). By doing this as soon as possible after ploughing, the land will work down to a fine tilth. Not only is the moisture thus better conserved, but the formation of clods, which are detrimental to after-cultivation, is avoided.

The general method of planting the potatoes is to put the set in the furrow behind the plough. Most of the growers use a cutter made out of an old chaffcutter knife. This is attached to the plough behind the mouldboard and is set to cut a part of the furrow off and leave a track for the man planting to put the potatoes in. I hope the day is not far distant when the planting will be done satisfactorily by a machine, so that the sets are placed at a regular distance apart. The depth to plant is about 3in. to 4in., so that the harrows will not pull the potatoes up.

The working of the land from now on depends on the quantity of weeds which will come before the potatoes make their appearance above ground, which takes from three to four weeks.

We harrow the land twice when planting, and it is a good practice to harrow twice about a fortnight after planting and twice more when the potatoes are up in the rows. This, I maintain, is the principal harrowing, as it is the last time we can get between the plants in the rows without using the hoe.

SEED.

I have spoken, so far, about the cultivation of the land, and now will touch on the quality of the seed and how to keep it.

The first thing to decide is whether to plant round or cut seed. If the former, it is best to pick over the small ones and take the best for seed, bearing in mind that they must come from potatoes that were cut the previous planting. In dealing with large potatoes for seed, it is a good plan to gather them from a part of the paddock where the crop was the best grown, and cull the very large potatoes out so that you do not have waste in planting; and you get a safer "come up" from the medium-sized ones. This way of selecting is a fairly safe one, but it is always desirable to have a complete change of seed every three years, or a few tons every year from which to raise your seed.

The manner of keeping the seed is important, so that we may get a good "come up" and also strong plants. The keeping of the potatoes in trays is a good plan, so that they become green and have short, strong sprouts when ready to plant. It is, in my opinion, far better than pitting or keeping in a barn. When one has from 50 to 100 acres to plant, however, it means a large expense and a good deal of extra work. There is a simpler way of keeping the seed, if not quite so good; but it is fairly satisfactory when planting a fairly large area. Most of the homesteads have a plantation of trees of some kind near the house. Make use of these by spreading the seed potatoes, one potato thick, under them, and leave them there until all have become green. One need not be afraid of frosts, especially under a thick bunch of trees.

STACKING SEED.

Let the potatoes lie on the ground for about two months. Then pick them up, put into bags, and stack the bags in single rows between the trees two bags high. This is done by passing a wire around the trunks of the trees, strained so as to catch the top bags about two-thirds up. Put the wire on before the bags are stacked. It can be left on from one year to another. When planting time comes the seed is carted out to the paddocks and distributed in lengths suited for the planter, and is cut there.

Generally, in the South-East, the potatoes are planted in rows which are about 28in. apart, and the sets are about 2ft. apart in the rows. No manure is applied around Mount Gambier, but in Millicent and Rendelsham it is used with good results.

We have now ploughed the land, planted and harrowed the crop, and the next operation is to scarify. The object in scarifying is to kill the weeds between the rows and loosen the ground ready for the moulder. I have mentioned the importance of avoiding lumpy soil. The scarifier will push lumps and clods to one side and leave them in the rows of potatoes. This is very detrimental to the crop, as when the potatoes are moulded the lumps are partly covered and they become a harbor for slugs and other pests, besides leaving the soil open, so that in the hot weather the moisture dries out quickly.

Finally, I would mould the potatoes. Some growers do not do this, on account of it drying the land very much. On the other hand, you have the advantage of not losing so many, when digging through greenness and worms. If the potatoes are left until the tops nearly touch each other between the row before moulding, the sun's rays have not such an effect on the soil. Set the moulder so as to leave a small gutter on the top.

THE DISCUSSION.

Mr. J. Brown (Port Elliot) would plough the ground to a depth of 12in. for potatoes, and plant the sets about 5in. deep. The potatoes developed above the set which was planted, hence the reason for putting it well down. The crop was improved by selection. It was well, when planting, not to use the very large tubers. A good plant could be raised from the crown eye. The system of keeping the seed which he adopted was to pick out the best, bag them until they just began to shoot, and then spread them out, rubbing off these shoots.

Mr. D. Tucker (Kalangadoo), who mentioned that the writer of the paper was one of the most expert growers of potatoes in the State, said that in his locality the soil was of a stiffer nature than that worked by Mr. Sassanowsky. He did not agree that a change of seed was necessary every three years. Careful selection would obviate the necessity for this. Some years ago he planted a variety which turned out practically a failure the first year. The following year the results were somewhat better. After having been grown for nine years they were at present much better than they were originally. Moulding was a matter that was governed largely by the class of soil. It was better to plant small tubers.

Mr. J. Darley (Narridy) thought that if potatoes were planted in October in his district they would be a failure. It was better to put them in during the first week in July; the risk of frosts must be taken.

Mr. J. Malcolm (Kadina) asked the best methods of cultivation for potatoes on the sandy loams of the Peninsula, and the best varieties to grow.

Mr. J. Dall (Woodside) asked the reason for bagging the seed after it had laid out for about two months. He thought the use of seed from very good roots would give as good results as would be secured if the large potatoes were picked out. He also desired to know whether spindly shoots would grow from any eyes that were cut through. It was a good plan to change the seed. Up-to-dates, especially, would be found to soon run out. Fresh seed obtained from Victoria would do far better than seed from tubers grown for two years in the locality.

Mr. G. R. Lines (Gladstone) drew attention to the manurial value of seaweed in connection with this crop.

Mr. A. Harper (Clarendon) advocated the frequent change of seed.

Mr. N. S. Giles (Mount Remarkable) thought it wise to give new seed a trial extending over at least three or four years before it was discarded as unsuitable to the district.

Mr. Sassanowsky, in reply, said harrowing after the crop was up could be done without danger. It did not pay to select the seed; the better plan was to change it. If they moulded the plants to too great a height there was a likelihood of a large percentage of small potatoes being secured. It was far better to have this, however, than to have a large part of the crop turn green. Potatoes dug in May or June could be planted in October. The reason he bagged the seed after greening was that if they were left out from May until October they would become very hard. By bagging them a mellowness was obtained, and as a result a better " come up " was secured.

RESOLUTIONS OF PREVIOUS CONGRESS.

Mr. G. G. Nicholls (Secretary Advisory Board), reporting on resolutions carried at the 1912 Congress, said the first matter he would deal with was—

SELLING CATTLE BY LIVE WEIGHT.

The resolution affirming that selling cattle by live weight should be given a trial had, at the previous Congress, been carried by a small majority. The Advisory Board had subsequently written to the Pastoralists' Association on the question, and that body had raised no objection to the proposal. The Abattoirs Board was then approached, and, after consideration, decided to take no action in the direction desired. There the matter for the present ended.

SELLING WHEAT BY LOAD OVER WEIGHBRIDGE.

The Advisory Board had written to the Chamber of Commerce in regard to this question, and the following reply had been received from the Secretary of the Corn Trade Section of the Chamber : " I am directed by my Council to inform you that in consequence of the number of centres in this State away from railway stations at which wheat is produced, and in view of the unfavorable reports received from the eastern States, where the proposed system is now in use, my Council are of opinion that your proposal to weigh wheat by load over weighbridges would be impracticable. They further desire to point out that the present method of weighing by single bags is found by traders and others interested to work most satisfactorily, and gives uniformity of custom throughout the whole of the State." He (the speaker) had also, under instructions from the board, written to the other States where the proposed system was in operation, and it was evident from the replies that there was a very mixed feeling in regard to the matter. There the question stood, but if anything came of the resolution carried that morning in regard to the marketing of wheat it would cover the previous resolution in regard to the weighing of wheat.

STUBBLE AND SCRUB BURNING.

At the last Congress prominence had been given to the trouble of burning stubble and scrub in dangerous months, and the inability to burn in safe months owing to the fact that the dates were fixed definitely by the Act. A resolution had been carried asking that the district councils should be empowered to fix the dates as well as the times of day when stubble and scrub might be burned. A Bill to consolidate the District Councils Act was before

Parliament, and provision was being made to give that power to the district councils.

Compulsory Registration of Stallions.

In regard to the resolution in favor of the compulsory registration of stallions, the question had been referred to the Branches, and of the 90 Branches that considered the matter only 71 expressed a definite opinion - 47 were directly in favor of the proposal, eight conditionally in favor, and 16 directly against. The matter had been referred to the Minister, who had sent it on to the Chief Inspector of Stock, who in turn had reported that at a a conference of veterinary officers in Sydney it had been agreed that uniformity of examination and certification of stallions could be attained. The conference had recommended that early legislation should be enacted to provide that uncertificated horses be not allowed to travel for stud purposes. It was considered to be highly desirable that stud books should be established in each State, and it remained for the Governments to decide as to the legislative measures to be introduced. He (the speaker) had communicated with the Minister of Agriculture that morning, and the Minister had replied that he would receive the minute and give full consideration to the resolution of the last Congress in the light of this further opinion coming from the Veterinary Conference.

Stud Book for Draught Horses.

The Director of Agriculture had been asked by the board to deal with the matter of a stud book for draught horses. He had written to New Zealand, and had gathered considerable information on the control of a stud book there. A few months ago the Director had referred to the matter at a board meeting, and indicated that he would suggest to the board that the Royal Agricultural and Horticultural Society should be the body to take up the formation of this stud book. He (the speaker) thought this matter would have been further dealt with had it not been for the unfortunate illness of Professor Lowrie.

AFTERNOON SESSION.

Mr. A. M. Dawkins (member of Advisory Board) presided.

SOME PROBLEMS IN STOCK-BREEDING

Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S., Superintendent of Agriculture in the South-East, addressed Congress on "Some Problems in Stock-Breeding."

Mr. Colebatch (who illustrated his remarks with a number of diagrams) said—I have chosen this subject of stock-breeding because I think it is one of interest to farmers in all parts of the State, and also because it is one which I thought wise to include in an agenda paper which generally contains so many items relating to wheat and wheat-growing. In speaking on the problems of stock-breeding I had either to include in this address a large number of problems and deal with them in a perfunctory manner, or confine myself to one or two of the more pressing and speak on them at a greater length. I have chosen the latter course.

INFLUENCE OF AGE ON REPRODUCTION.

The age of the animals selected for breeding purposes, at the time of mating, has an important bearing on certain phases of the reproductive processes. In a general sense this may be said to be a well-recognised fact amongst stockmen, but much difference of opinion obtains as to the precise nature of the influence of age both on the parents and the progeny, and correspondingly we find widely differing practices are being adopted, according to the tenets and beliefs of the individuals responsible.

It is not always possible to adhere to systems accredited by both science and traditional experience. Circumstances may arise that make it expedient to depart from well-proven methods, but it will be well for us all to keep the known facts prominently before us, so that whenever discretionary power is within our grasp the opportunity of turning it to best account may not be lost.

An examination of the subject of the influence of age on breeding problems enables us to divide it up into several sections as follows: 1. The time to commence breeding. 2. The time to cease breeding. 3. The rate to continue breeding. 4. Influence of age on mating systems. 5. Influence of age on fertility. 6. Influence of age on quality of progeny.

INFLUENCE OF AGE ON PRODUCTIVE PERIOD AND RATE OF BREEDING.

We will discuss the first three sections together. The age at which animals should first be used to propagate their kind has been the subject of controversy from very early times. Even to-day we find two schools of opinion persisting, but the steady diffusion of knowledge regarding the principles of general and sexual physiology will in time remove many of the misconceptions which have grown up round the subject. In his work on "Horse-breeding" Reynolds sums up the position in general terms when he states that "subject to the influences of early precocity or contraction of disease, the age at which draught stallions and mares may be employed for breeding purposes is prescribed only by the natural development and decline of procreative power, but the periods of life when they may be profitably used are more limited." The last section of this statement touches upon one of the most important aspects of the whole problem. The question of the age at which to start farm animals breeding resolves itself more or less into a profit and loss calculation. "Breeding from babies," as early mating is sometimes called, may be warranted under certain special circumstances, but most will agree that the general concensus of opinion amongst breeders of to-day is opposed to the practice of mating either male or female stock before they have had time to ensure the proper development of their own frames and constitutions.

Prominent amongst those who advocate the mating up of immature animals is Captain Olver, who, in his article on the "Hygiene of Breeding" says in reference to young stallions, "It is a pretty general custom to allow him to serve a small number of females at quite an early age, and gradually increase the number; and we think this is the best system, provided that great care is taken to prevent him doing too much work until he is fully developed." Further on in the same essay he goes on to say --"In the case of the female, also, we think it is a good system to get her to breed at quite an early age, provided she can be maintained in extra good condition throughout the period of pregnancy and subsequently." Both these statements are rather vague, inasmuch as the phrase "quite an early age" admits of many interpretations; but it seems clear, from the cautious character of the provisory clauses, that the author had in mind breeding from animals that were not sufficiently developed to exercise their procreative faculties without calling for special care and attention to enable them to come through in healthy, thrifty condition.

Amongst breeders of racehorses, pedigreed stock for special purposes, and fancy breeds of all classes, such advice might be well received, as every care is bestowed on the stock that constitute studs of this character; but it is just that extra special attention that the animal employed in trade breeding is in very great danger of being compelled to do without. On this account, and for other reasons shortly to be referred to, early mating under ordinary farm conditions is apt to be dangerous to a serious degree. A better grip of the facts will be obtained if we consider closely the arguments put forward by the advocates of both systems.

Those who adhere to the practice of early mating do so for the following reasons:—

1. They claim that experience has demonstrated that the progeny of such unions are frequently of high quality and stamina. Many notable instances may be cited in support of this contention. The famous shire champion "Bury Victor Chief" which won the Challenge Cup of the society in 1894, and which changed hands two years previously at the record price of 2,500 guineas, was foaled by Bury Daisy at 3 years of age. Evidence of this kind, however, is not convincing, for it should be remembered that "of the huge total of animals so bred, those which have achieved fame at the ring or at the stud form a very small proportion and lend no sort of encouragement to the adoption of early breeding as a general system." Indeed, it is more than likely that the proportion of animals thus bred which have thereby been handicapped out of the struggle for distinction far exceeds that limited proportion which has reached the front rank.

2. It is further asserted that no apparent ill consequences follow as long as good judgment is shown. In reply it may be said that so far as apparent evil effects are concerned it is difficult to form an opinion, inasmuch as it is beyond any man's power to gauge the inhibiting influence of early breeding on development. Comparisons with similarly bred animals that have not been mated early may be interesting, but they can never furnish criteria on which to form sound judgment. It is probable that the deterioration is a gradual process, and whilst not strikingly apparent in a single generation, being cumulative, it will ultimately come to be plainly observable. Defects that are traceable to this cause are usually very difficult to eradicate. In any case, if applied to any but the most experienced breeders the argument must be regarded as unsound, since it leaves far too much room for the display of faulty judgment.

3. Early breeding is said to be beneficial in that it causes the generative system to attain its full development at an early stage in growth, when the frame is capable of considerable expansion and modification of form. In this way it is believed to lessen the risk at subsequent births, and so enhance the value of the animal as a safe breeder. The truth of this will be generally conceded, but it must not be overlooked that there is a higher mortality from difficult parturition amongst animals that have been bred very young than in the case of those that are better grown. And again, although much stress has been laid on the mouldable nature of the skeletal and other structures in the immature frame, the pelvic girdle will still respond to the normal expulsive efforts during birth when the physical development is a little nearer completion.

4. Those that have bred early are said to be more reliable as breeders. So far as can be ascertained, this conclusion has not yet been substantiated by reliable data. On the contrary, statistics would appear to show that very young animals are not generally reliable as breeders, and there is difficulty in finding a reason for supposing that animals bred before mature are on that account more trustworthy as breeders.

5. In precocious animals with high spirits there is less danger from accidents, and in the case of some male animals less risk of vicious habits if early mating is resorted to. This is good sound reasoning, and as an argument in favor of early mating in special instances it will be supported by most breeders. The check to development in unbred heifers through the frequent recurrence of "heat" (two or three days every three weeks) is advanced by dairymen as a reason for early mating. Such cases of necessity, however, are far too infrequent to justify the general adoption of the system.

6. In the case of high quality stock it is often deemed desirable to ascertain the breeding qualities at an early age, and further, under certain market conditions, it may be advisable with certain classes of stock to sacrifice, temporarily, future interests for immediate profits by instituting early breeding.

The possibility of temporarily resorting to early mating advantageously under special economic circumstances must be granted, but such practices should not be preferred as justification for according support to the view that under ordinary working conditions breeding from babies is better than breeding from well-grown stock approaching maturity.

Wortley Axe, who strongly discountenances the use of partly-grown animals for stud work, has laid it down that " no one with any knowledge of the laws of life can doubt that to impose upon a mare the task of reproduction whilst actively engaged in building up her own frame, and to ask her subsequently to support her offspring, is a certain means of retarding her growth, if it does not also enfeeble her constitution." In other words, it is to be regarded as a distinctly risky process that cannot be supported on any sound physiological grounds. It has been truly said that the highest physical development is reached when the nutritive resources of the system are devoted exclusively to its own maintenance and not shared by the growing fœtus. By draining the body through the generative organs before maturity has been approximated to, the size, condition and general health are apt to be impaired, and it is important to remember that an impaired constitution means increased susceptibility to disease and diminished recuperative powers. Having regard to the dangers attendant on prolonged convalescence, the advantage of breeding and rearing strong, hardy types is very evident.

A further reason for inveighing against the prevalence of early mating is the danger of abuse to which the system lends itself. The attendant evils will naturally be more apparent in the case of females, but much harm may also result in the case of males by over use and over stimulation through high feeding and possibly drugging.

In actual practice it is not contended by many that physical growth and development should be complete before the sexual powers are called into action. Saunders has observed that " there is no horse but would be the better for absolute continence until he is fully matured," and no doubt from a physiological standpoint this is strictly correct; but, as already stated, the question cannot be settled without reference to the economics of stock-breeding. There are undoubtedly advantages to be gained by not waiting till the maturing processes are absolutely complete, and experience teaches that under domestication it is possible to reap these benefits without detriment to the breeding stock. It is, however, regarded as essential that as a general rule what may be termed the critical period of growth—that is, the period in which the proportion of assimilated food utilised in the formation of new tissues is high, relative to the amount required for purely maintenance purposes—should have elapsed before the reproductive functions are exercised. The actual stage of development when this critical period has passed will differ with the class, breed, and individual; but experience has prescribed the ages at which stock-breeding may be safely commenced under average conditions. These we may now consider in connection with the different classes of farm animals.

HORSES.

With colts the usual practice is to allow a few mares when two years old, but unless there are special reasons for doing so it would be better to defer service till a year older. With well-furnished colts that are too "fresh" to settle down properly, an allowance of eight or ten mares may be given. It is better to let the services follow quickly on one another, so that the stud work may be soon over, and the colt will then be more likely to calm down and develop his system without fretting, than if the stud work be distributed over a long period of time. As three-year-olds an allowance of from 20 to 40 mares for the season will be sufficient. This gives a fairly wide range, and discretion must be shown, for it is known that there is a vast difference between the sexual proclivities of animals of the same breed and strain.

I would draw special attention to these figures in respect of three-year-old stallions, as I am inclined to think that many of the New Zealand and Victorian colts of that age which have found their way into this State have been worked at the stud far more than they should have been, and their conformation and reputation as sires will in many cases have suffered as the result. Even in older countries, where breeding stock are housed most of the year and fed heavily with concentrated foods, it is not advisable to exceed the above figures as a general rule, and it is hardly likely that greater liberties can be safely taken under our system of working. When four years old from 50 to 70 mares would be ample, and on reaching maturity in the fifth year the number may be raised to 90 or 100 per season. If stallions were brought to their work gradually in this manner there would be small need to resort to arsenic, strychnine, yohimbine, or other aphrodisiac drugs to pull them through the season. Furthermore, there is a grave danger that colts that have been used to excess when young may give way in the hind legs and become temporarily, if not permanently, impotent. With reference to stallions in full use, the number of mares served—within reasonable limits, of course—seems to have little effect, provided the condition be maintained; but if this knowledge be taken advantage of, and the horse be used to excess for a long period, partial or complete loss of virility may ensue.

In the Government breeding studs of Germany it used to be held that better results would be secured by restricting the number of mares to 15 or 20 per horse, but they have gradually increased the allowance, till to-day a stallion in full vigor is allotted 100 or more. From the official statistics of horse-breeding in Saxony it appears that the highest percentage of foals over a period of seven years was obtained from horses serving from 80 to 100 mares, and similar results were secured with the French studs. The number of mares, however, must be varied with the known capacity of the animal and the condition and vigor, which will themselves vary from season to season. Naturally a horse that succeeds in stinting his mares with very few services will be able to take more than one whose mares are continually coming back to him.

Fillies are commonly bred from as two-year-olds, but in my opinion this is a practice that, except under special circumstances, cannot be too strongly condemned. Fairly well-grown stock should not be mated till the spring of the third year, and if at all backward they should be held back till rising four years old. When young mares have been stinted as two-year-olds it is advisable not to subject them to more work than is necessary to break them in. They should be allowed to rest from the time of conception till the foal has been suckling for at least two months, and they should be well fed the whole time. It is usual to allow them to miss breeding the following year in order to develop their own expanded frames, and their second foal will then be dropped in the fifth year. As a general rule, however, biennial breeding is to be discouraged. In properly nourished stock it is found that the mares do better and breed better if they conceive every year, and naturally mares that produce a foal annually are more profitable to the breeder. The generative organs appear to lose their tone and are apt to undergo degeneration if the intervals between the births is unduly prolonged ; and it is better, therefore, to feed well and keep the mares breeding regularly from maturity onwards. Mares that are brought to the stud late in life are rarely a success, owing to the atrophied condition of the organs of reproduction through disuse, and even if they do breed and are judiciously mated the foals are generally unthrifty weaklings.

CATTLE.

Amongst dairymen it is often considered advisable to calve down heifers at two years of age, for the reason that it is thought this early breeding has the effect of strengthening and encouraging the free flow of milk. If the heifers are subsequently kept milking as long as possible, and the second conception be deferred till late in the lactation period, there is little doubt that the system has an influence in this direction ; but is not this advantage likely to be gained at too great a cost ?

It has been argued that the case is not on all fours with the early breeding of horses, where the development of bone and muscle are of pre-eminent importance. In dairy stock we are concerned with the milking capacity, and are therefore primarily interested with the number and activity of the secreting cells of the udder. It is impossible, however, to get away from the fact that breeding continuously from immature and undersized stock will in the end result in the production of smaller types and in the weakening of the constitution. Such early mating will be followed by arrested development of the mother, loss of stamina in the calf, and unless the choice of heifer has been well made and the food supply well maintained, there is a distinct danger that both mother and offspring may become irretrievably stunted. By holding back for another four to six months the loss of time incurred through having to defer the second mating of early-bred heifers is not experienced. With very forward heifers, or those that are being retarded in growth through sexual excitement, early mating may be justifiable, but when the progressive improvement of the herd is the purpose in view it will be found better general practice to defer calving till heifers are not less than 28 months or two and a half years old. There will then be less trouble in calving, and all the benefits claimed for earlier mating will still apply. I refer to such statements as that pregnancy has a stimulating effect on the system, encouraging assimilation and hastening growth, and also that it is easier to develop the milk-secreting organs at an early age. Amongst beef-breeders the necessity for breeding from well-grown stock is well known, but in pedigreed herds, where it is so important to get an early hint as to the breeding qualities, early mating is frequently resorted to.

Bulls are usually purchased very young, and the tendency is to use them on the herd far too early. In farm practice they are better not used whilst under 1 year old. Between the ages of 1 and 2 they are not likely to suffer by being allowed, say, 15 or 20 cows, and when over 2 they may be used freely till their powers begin to fail. Bulls of the heavy breeds are usually less prolific than the lighter and more active types, but an average allowance for bulls in full vigor of from 60 to 80 cows is not excessive when the services are well distributed.

SHEEP.

In order to keep up the lambing percentage the ewe flock is generally well culled for age each year. In the warmer areas of this State, where development is very rapid, it is usual in farm flocks to mate up the hoggets, but in the southern districts such early mating is too often followed by a disastrous lambing. It is very largely a matter of growth and condition. The pernicious effects of continuous early mating will undoubtedly apply as much in regard to sheep as in other animals, but as the hoggets form only a proportion of the breeding flock the resulting deterioration would be obscured, and the annual culling of poorly developed ewes will act in a measure as a corrective. Moreover, when Merino two-tooths are mated there is generally a fair percentage that fail to get in lamb. In actual practice, therefore, it is difficult to perceive any injurious results, and from the pecuniary standpoint the advantages of mating hoggets are quite obvious. This, however, must not be taken as a proof that the physiological principles on which the objections to early breeding are based may be safely set aside. Were sheep-breeders to restrict their operations to the mating of hoggets for a season or two the loss of constitution, loss of size, and increased losses at lambing time would soon become apparent. In the hands of careful men it is possible that the system may be employed in suitable localities without undue risk; but, in order to get the best results by it the feed must be plentiful and the hoggets practically as well-grown as four-tooths in colder climates.

A few years ago the use of ram lambs became fashionable in certain parts of England, as it was held that they got a larger percentage of twins. The theory was inquired into by W. Heape, at the instance of the Royal Agricultural Society, and he was able to show that the ram lambs were in no way responsible. He proved that in those flocks where ram lambs were used with this object a full share of twin lambs were dropped by portions of the flock that had not had access to ram lambs. The same practice was tried in this State, but as Mr. Jeffrey observes in his book on "Sheep and Wool," "It is noticeable that many who adopted this practice have since discontinued it, and they are content to wait till the ram has further developed." Four-tooth rams should not be allotted the full number when worked separately, as they are not then fully grown. About half the usual number will be sufficient, but after that age they may be given from 50 to 100 ewes according to their condition and age. Where fat lambs are being bred for young rams are much to be preferred, as being likely to increase the rate of growth and aptitude to fatten.

PIGS.

As in the case of other stock, when pigs are bred too early they suffer in themselves and produce degenerate litters. Since they are generally forced along with abundance of rich food their sexual propensities develop very early, and there is a temptation to mate them up before they are well grown. Some use them at 6 months, and others hold them back till they are a year old, but it may be considered quite safe to breed either boar or sow at 8 or 9 months.

INFLUENCE OF AGE ON FERTILITY.

Reasoning by analogy from the conclusions of Duncan with reference to the human species, it would appear that the fertility of female animals rises rapidly from a condition of sterility to a climax, and then declines again very gradually till sterility is again reached. Probably the same is true of males, but in their case the change from initial sterility to the highest degree of fertility would seem to be more abrupt, and the ability to procreate appears to persist longer.

The following table sets out the extreme limits of age at which breeding has been known to occur in farm animals, and it also shows the duration of the profitable breeding period.

	Earliest Age.	Latest Age.	Profitable Breeding Period.
Mare	11 months	38 years	3 years to 15 years
Cow	2 months	29 years	2 years to 10 years
Ewe	3 months	24 years	1½ years to 5 years
Sow	3 months	—	8 months to 6 years

Although the useful productive period for mares is given as from 3 to 15 years, the procreative powers of many begin to fail at about 12, and reliable breeders well up in the "teens" are by no means common. Similarly in the case of cows, breeding becomes too uncertain after 12, and sometimes they will require culling a year or two earlier. Ewes vary considerably in the age at which they cease to breed regularly. Some are unreliable at 4 or 5 years, whilst others may continue till double that age; but as they are generally cast when they begin to break in the mouth, they are rarely kept for breeding after the profitable period has elapsed. Sows generally breed satisfactorily till 5 or 6 years old, but they are inclined to become vicious and clumsy as age advances, and are not often retained till their breeding powers are on the wane. Stallions have proved themselves fertile before 12 months, and, according to Aristotle, have been known to beget foals at the age of 40. It is difficult, however, to discover evidence as to the effect of age on the procreative aptitude of male animals.

The highest percentages of foals begotten at the Saxony studs for the six years 1856-61, inclusive, were sired by horses of widely differing ages, as shown in the table—

	Highest Percentage.	Second Highest Percentage.	Third Highest Percentage.
1856	6 years	19 years	12 years
1857	4 years	20 years	14 years
1858	9 years	10 years	5 years
1859	Nearly uniform in all ages		
1860	17 years	18 years	19 years
1861	Nearly uniform in all ages.		

In the succeeding year the 10-year-olds headed the list, whilst the 20-year-olds threw twice as big a percentage as the 4-year-olds. These results are interesting, and they appear to bear out the view that fertility in the male sex is less a matter of age than a question of condition and management. Another remarkable record which is pertinent to the subject is that of the famous American trotting horse Rysdyk's Hambletonian 10. This stallion was at the stud for 23 years—he was not used in 1868—and threw 1,331 foals from 1,930 mares, which works out at 69 per cent. The average number of mares served per annum was 83. If we except the last year, when his health was evidently breaking up, it will be noticed that the yearly percentage of foals begotten was exceedingly uniform, and that the fertility was scarcely if at all, influenced by the age of the horse.

German Breeding Studs.

Before leaving the subject of the fertility of stallions, it will be instructive to refer to the results obtained at the Government breeding studs in Germany. The records have been carefully kept for a series of years, and by combining the results of the 11 breeding stations over a period of 15 years the average percentages for over 1,000 stallions and 42,000 mares per year work out as follows:—Average percentage of mares in foal, 67·7; average percentage of live foals dropped, 53·3; average percentage of abortions or miscarriages, 4·8; average percentage of mares dying or not accounted for, 9·6.

Considering that these results are the averages for a total of 15,000 stallions and 630,000 mares that have had the benefit of good management they may be expected to be slightly above the general average under ordinary farm conditions. Country stallions have frequently to accept mares that are utterly unfitted for breeding, and their percentages will suffer accordingly, but on the other hand many good horses will come through the season with much higher results than the average secured in the official studs of Germany. If we assume that the above figures may fairly form a basis for calculation in our own State, the stallion that is advertised to stand the season for £2 could,. with a booking of 100 mares, afford equally well to stand at the rate of £1 down and £1 10s. when the foal is proved, or £1 down and £2 on the production of a living foal. In practice no doubt this margin would be found too narrow, but the figures will serve as a means of comparing the risks in the case of sound, healthy horses that are entitled to be called "sure."

Unfortunately there are no reliable data available as to the records of fertility in other classes of stock. It is everywhere admitted that in multiparous animals the first litters are smaller in number than those obtained later in life, and it is known that twin calves or lambs are rarely the result of first impregnations. The same general conclusions, however, may be safely applied in all cases. Age is not without its influence on the extreme limits of the producing period, but as a determining factor during the profitable breeding period it is of much less importance than the proper dieting, housing, and general management from babyhood to parenthood and throughout the stud career.

INFLUENCE OF AGE ON QUALITY OF PROGENY.

One frequently hears it said that very young and very old animals are less likely to produce offspring as robust and of as good quality as those in the full vigor of life. The subject has not been very closely studied, and we are as yet unable to say to what extent the fitness and keenness of the animals when mated may influence the vitality and development of the resulting progeny. It is reasonable, however, to believe that they have such an influence, and therefore it is a point that all stock-breeders should take into their calculations. To some extent the inferiority of the progeny of many young animals may be due to the fact that in primiparæ the milk glands are often insufficiently active, and the progeny is in consequence deprived of a good measure of that share of " breeding " which is said to " go in at the mouth." Matrons also are rightly regarded as better mothers than young dams, and their offspring gain a better start in life. In the case of old age in either male or female improvement is less likely to result by breeding, and the offspring will in all reasonable probability be born in a poorly nourished condition, and, if reared, will be small and weedy. It is a common practice on many farms to retain favorite old mares after they have been pensioned off and let them breed, but in many cases I am convinced it would be kinder and less costly to let them end their days in peace.

We have next to consider whether differences in age within the limits of the period of profitable breeding will affect the quality of the progeny. The term quality may refer either to symmetry of form and character of hair, skin, bone, and tendon, or to ability to perform well on the track. In both cases, however, the age of the parents within such limits would appear to have little or no influence. The old English blood mare Pocahontas bred Auracaria (a noted brood mare) at 25 years. Hambletonian X. sired his fastest son when 8 years old, his next fastest at 16, and the next at 21. Electioneer's three most noted gets were sired at 17, 13, and 21 years respectively, whilst Volunteer produced his best at 12, 9, and 7 years. Examples might be multiplied indefinitely, but sufficient have been quoted to confirm the statement that, if judgment be shown in the mating, stock of high quality are as likely to be produced towards the close of the profitable breeding period as at the commencement or during the middle phase.

INFLUENCE OF AGE ON MATING SYSTEMS.

It has already been pointed out that both young and old stock are uncertain breeders, and it is therefore possible to understand why the best results are not obtained when the influence of age is overlooked. In practice it is found that in order to secure a high percentage of increase, and to favor the production of the best quality stock, young females should be mated with vigorous well-seasoned males, whilst those that are approaching the finish of their breeding careers are better put to sires that still retain the freshness and vitality of youth. The combination of young females with robust males is more likely to bring about successful " nicking " than the use of old females with young sires; and after all it is every breeder's ambition to so blend the strains as to enable him to make some appreciable contribution to the improvement of the breed. When dealing with stock that are in their prime the choice of suitable mates will depend on physical and temperamental characters and on the known breeding capacity, but preference will generally be given to sound hardy types that have passed through the early stages of their stud work.

RELATIVE INFLUENCE OF SIRE AND DAM.

There has been a vast amount of speculation in regard to this subject, and, as is usually the case with vexed questions, very decided opinions are held concerning it. Many writers have dealt with the matter, and they have varied a good deal in their views. Some have maintained that the male parent influences more particularly the musculature and general outward appearance, and so affects chiefly the conformation and locomotory powers, whilst the female is responsible for the development of the internal organs. This, I believe, is a very popular theory amongst practical men, and as such is deserving of searching examination. There will arise in the minds of breeders of livestock instances within their own experience that appear at first to offer irrefutable proof of its accuracy, but in the great majority of cases the confidence reposed in this ingenious theory will be found to rest on second-hand evidence and tradition. Various modifications of this theory are revealed by a study of the literature on the subject. Other writers aver that the male determines the conformation of the forehand, upper parts of the body, and extremities, also strength and mental qualities. In this instance the female controls the height, volume of trunk, and posterior conformation. Again, it has been said that it is reasonable to expect that each parent will be particularly liable to influence the characteristics that are specially developed in the sex to which they belong. In other words, it is to be anticipated that the masculine attributes of the progeny will be traceable to the sire and the feminine attributes to the dam. Further, on account of the intimate and prolonged connection between the mother and offspring, it has been assumed that the influence of the former in moulding the character of the young will predominate.

Thus it is seen that there is a great diversity of opinion as to the relative influence of the sexes amongst those who believe that it is possible to confine the direction of growth and development within the narrow limits of a so-called "law."

Observant breeders must have noticed that even offspring of the same parents frequently exhibit such diversity of type and character that it is by no means an easy matter to detect marked resemblances to either sire or dam. It is true, of course, that instances of prepotency are very numerous and at times very striking, and when it happens that a sire possesses in marked degree the capacity to stamp his own likeness on the bulk of his progeny it is possible that the temptation to generalise from insufficient data may lead a man to think that perhaps the male does affect more particularly the outward appearance of his offspring. So far as is known, however, there are no good grounds for thinking that when parents of equally pure lineage and strength of character are used the development of the young will be influenced more by one than the other. The problem is not one that can be readily submitted to experiment. Even if it were feasible to eliminate the confusing effects of atavism, variation, and prepotency it would be profoundly difficult to solve, and with Nature's laws unfettered it becomes infinitely more so. All that can be said at present with any pretension to accuracy is that under ordinary conditions the "laws" of prepotency, reversion, and variation suffice to explain the experiences that favor the theory of relative influence of the sexes, and that when none of these "forces' are in operation the process of development will be influenced by the parents in an equal degree. (Applause).

REPLIES TO QUESTIONS.

Mr. A. Beviss (Strathalbyn) said he had had 38 years' experience in horse-breeding, and he considered that the address given by Mr. Colebatch was the most exhaustive and instructive he had ever heard. (Applause.)

In reply to questions, Mr. Colebatch said stallions that were kept in countries where the natural feed was better and stronger were more capable of serving a large number of mares than those kept under Australian conditions. Whilst he thought there were many horses in Australia that were sufficiently strong foal-getters to cover a hundred or more mares and get a high percentage of foals, there was also a large number that would be better with half that number. There was room for a good deal of improvement in the way some of the stallions in this State were kept. Farmers whose mares were being put to these horses should interest themselves in the number of mares that each was serving.

Mr. W. H. Smith (Naracoorte) congratulated Mr. Colebatch on his excellent address. He desired to know whether it was better to breed " bone to bone " or " hair to hair."

Mr. Colebatch did not think they could afford to discard the importance of a certain amount of hair. Farmers should endeavor to breed a good class of bone ; where this was secured, generally the quality of the hair would be all right. If the hair were too fine, this would be secured at the expense of the bone. They should aim at the average by trying to breed quality into the coarse mares and roughen up those that were getting too fine.

Mr. A. L. McEwin (Blyth) said the first foal from a young mare would generally follow the horse very closely ; older horses should be used on these, but subsequently younger horses should be used.

Mr. J. Brown (Port Elliot) asked whether the crossing of a mare with an inferior horse affected the subsequent foals.

Mr. Colebatch did not think an absolute case of telegony had ever occurred. Like the question of transmission of mutilations, it was one of which positive proof could not be established. All that was established was that it could not be experimentally produced. Experiments had been made with all classes of stock, and in not one single instance had it been established. Several cases which appeared to be instances of telegony could be well explained by ordinary natural laws.

Mr. W. B. Russell (Loxton) asked whether stringhalt was caused through the early use of stallions.

Mr. Colebatch replied that the cause of this trouble was not definitely known. Anything that would tend to tax the muscular supply in a beast that was predisposed to the disease would probably bring it on.

Mr. J. B. Beck (Wynarka) asked whether it was advisable to have a mare served twice.

Mr. Colebatch said there were many mares which were highly strung and which were unable to retain the seed of the stallion long enough for impregnation to occur. In these cases the first service would go a long way to allay the excitability, and with the second service there was a greater chance of success.

Mr. H. Billinghurst (Crystal Brook) asked whether a percentage of 67.7 per cent. was considered a fair average get in this country.

Mr. Colebatch thought the percentage for this State would not exceed 50 per cent. In so far as travelling stallions were concerned, a better system would be for the risk of the foal to be borne by the two contracting parties. Farmers were well advised to pay a little for the insurance of the foal.

IRRIGATION ON THE FARM AND GARDEN.

Mr. A. J. Bray (Gawler River) read the following paper dealing with "Irrigation on the Farm and Garden":—

The practice of irrigation is of ancient origin. The ancient Greek and Latin writers make reference to its use. The Egyptians, Babylonians, and Phœnecians excelled in the art Many of their embankments and aqueducts were of a nature which modern engineering science would not despise. Their methods of raising water were in most instances of a very primitive nature; and it is in this direction that the greatest advance has been made. Australia is a country subject to periods of shortness of rainfall. Water conservation and means of irrigation are essential to the regular production of garden produce and summer fodder. A bold policy of water conservation, where practicable, would do much to lessen the disadvantages of periods of drought. If water which now flows to waste in many of our watercourses during the rainy season could be conserved, hundreds of acres could be irrigated. Summer fodders could be grown to the great advantage of the dairying and other industries. Plots of early autumn and winter feed could also be started by its agency. In some irrigation settlements the producers depend almost entirely upon irrigation for their supply of moisture. I do not, in my paper, intend to deal with conditions such as these, but rather with those where irrigation is resorted to as a means of supplementing the natural rainfall. Where surface water may be impounded in dams or reservoirs, distribution is by means of channels, fluming, or piping. There are many localities where no such supplies are available, but below the surface water may be obtained by sinking. Where water is procurable by means of wells or bores, appliances are required for raising it. Of motive powers commonly in use the windmill is the cheapest. True, the driving power is fluctuating and somewhat uncertain, but if storage be provided, the windmill will raise sufficient water to irrigate small areas of garden or fodder plots. On many farms windmills are in vogue as a means of raising water for stock. The capacity of the mill and the water supply are often greater than the requirements of the stock. Under these conditions what is simpler than to lay down a plot of lucerne and irrigate it with surplus water?

RAISING THE WATER.

I have not had opportunity for actually testing the results of large mills with direct action, or smaller geared mills, but from observation I believe that in a given time the smaller geared mill will give better results, especially with wells of a fair depth. The light winds, which fail to drive the larger direct action mills, keep the geared ones in motion. The advent of the oil engine has provided a power which is eminently suitable for driving irrigating plants. The motor or petrol engine may possess advantages in the matter of quickness of starting, but the oil engine, being heavier in construction of slower speed, and less costly for fuel, will, for constant work, prove most satisfactory.

A good margin of power is always advisable in oil or petrol engines, as if working up to the limit, there will probably be stoppages and loss of time. For wells of shallow depth, centrifugal pumps give good results, throwing a large stream of water. Their cost is also very moderate. Where, however, the water has to be carried a distance, or the lift is more than 40ft., force pumps will prove more satisfactory. In regard to underground water supplies in the form of springs, there is yet much to learn. While divining rod experts may not be infallible, it seems that there is some basis for the belief that water supplies can be discovered by the agency of the divining rod. The matter is one worthy of close investigation, as the presence of good underground water supplies at a reasonable depth opens up great possibilities in the way of irrigation, and, by its agency, intense cultivation. If the divining rod expert could with reasonable accuracy reveal the best localities on which to sink, the probable depth, and supply of water available, much useless expenditure of labor and capital could be avoided. Springs vary very considerably in quantity, quality, and depth, a few chains interval often giving very different results. The subject is of such importance that further investigation by experts would seem justifiable.

QUALITY OF WATER.

One question of great importance in irrigating is the quality of the water. Unless the different results upon trees or even lucerne by irrigating with different qualities of water had actually been seen they would hardly be credited. A gentleman in Gawler had some orange trees which were irrigated with water from the Gawler reservoir, when supplies were obtained by pumping from a well in the town. They were miserable specimens. When the town was supplied with water from the Barossa reservoir, and the trees irrigated with this, the changed appearance was marvellous. In every other respect the treatment was the same, but the different water transformed the trees. A fruitgrower on the Gawler River some seven miles below the town irrigated his orange trees freely with water from that river. The result was disastrous. The proportion of minerals present in the water during the summer months was so great that the trees were being poisoned. Since the same trees have been irrigated with water from the Barossa reservoir a marked improvement has resulted. The trees, which bade fair to die out, are now profitable. Where the results of irrigation seem unsatisfactory, an analysis of the water would often give a solution of the trouble.

Humus Supply.

Where irrigation is resorted to, it is necessary to apply manure. Irrigation tends to consolidate the soil and remove the organic matter. Stable manure is, of course, the best to apply, but where not available any form of vegetable matter will prove beneficial in keeping up the supply of humus in the soil. Continuous irrigation, without such replenishing of organic matter, tends to sour the soil. This explains why gardens once flourishing seem no longer to maintain their productiveness and the soil to have lost its openness and fertility. The fruitgrowers of the irrigation settlements in the Goulburn Valley, in Victoria, have had to change their methods on this account. Where formerly, by careful cultivation, they never allowed any weeds to grow in winter, they now find it necessary to encourage their growth. They sow peas, barley, &c., for the purpose of ploughing in, in order to keep up the supply of organic matter and prevent consolidation.

Cost of Water.

The question is sometimes asked as to whether it will pay to irrigate with water at 6d. per thousand gallons, the price for excess water in some of the water districts. I am doubtful as regards lucerne or other fodders whether it will on a commercial scale. I believe, however, that it will pay every keeper of stock to use water at that figure, if no cheaper supplies are available, to grow a small area of lucerne or other fodder. Such fodder, though not available as a regular article of diet, will, if used occasionally, when no other green feed is available, tend to keep stock healthy, thus proving a profitable investment. The fruitgrower can profitably utilise water at 6d. per thousand. One or two applications of water to trees when fruit is maturing often make all the difference between success and failure, and transform an indifferent sample into a good, marketable article. Even citrus trees, which require more moisture than deciduous trees, can in most seasons be profitably irrigated with water at 6d. per thousand. Cultivation after each irrigation prevents rapid evaporation, thus enabling the producer to do with less water.

Means of Watering.

Producers differ as to whether it is more profitable to apply water by means of sprinklers or surface watering. Where the subsoil is of a clayey nature and not too absorbent, I favor surface watering. On limestone rubble formation or uneven ground the sprinklers are the only satisfactory means of evenly distributing the water. It is claimed that the sprinklers most nearly approach the natural rainfall; but too often atmospheric conditions are not in keeping when the moisture is being applied, and there must be immense waste by evaporation during hot winds. My personal experience has been that vegetable plots in summer time thrive better with surface irrigation by means of drills than by overhead watering by sprinklers. Where an abundance of water is available, flooding the whole surface will prove most satisfactory. The soil must, of course, be graded, and if of a porous nature, divided off into small sections. When irrigating trees, especially large ones, as much as possible of the surface should be covered with water. Too often when water is applied in narrow rings the outside roots do not reap the benefit of it, and accordingly they suffer.

In conclusion. The benefits of irrigation are undoubted. The question the producer has to consider is not whether others in more favored localities can profitably irrigate and reap advantages beyond his power to gain, but whether, under his conditions, it will repay him. The advantages of a supply of green fodder during the summer months to the dairyman are undeniable. Irrigation, in ordinary seasons, alone renders this possible in many localities. A large increase in water conservation and a greater resort to irrigation will prove to be important factors in developing the rural industries of the State. (Applause).

THE DISCUSSION.

Mr. Ricks (Cherry Gardens) considered the question of irrigation one of the most important producers could discuss. Mr. Bray's paper contained a lot of practical commonsense. He personally was getting a living off 20 acres. He had two sons—one 28 years and the other 15 years; he also employed a married man, and they were all working on the 20 acres. That was a result of irrigation. They had an oil engine and conveyed the water to where it was wanted in pipes, using sprinklers. His experience should encourage those who had a supply of water to make good use of it.

Mr. W. H. Waters (Renmark) said he had occasion to know that Murray water at low periods of the river was very injurious to plant life. His idea of a model irrigation block was reclaimed land where the water was let on the land and then pumped out by means of drainage.

Mr. J. Malcolm (Kadina) said with proper manuring and judicious watering he could make irrigating pay at 2s. per 1,000galls. for water. His farm was on the coast, and he could assure those similarly situated that if they used the seaweed for bedding and afterwards as manure they would find a wonderful improvement in the production of the soil.

Mr. H. Billinghurst (Crystal Brook) said the question of the cost of water was very important, and one that might well be considered by Congress.

He would like to know, seeing that the reservoirs were the property of the whole of the people, why those living in the north should be charged so much more for water than were those living in the south. He moved—"That in the opinion of this Congress it is advisable that the Advisory Board bring the question of the difference in the charges made for water before the Government in order that producers living in the north may get some redress for what is considered a very great grievance."

A delegate did not think those served from the Beetaloo and Bundaleer reservoirs should be charged more for water than people in the more favored districts. He seconded the resolution.

Mr. Malcolm asked the opinion of the Chairman as to whether the putting of the motion would not be introducing politics.

The Chairman said he did not think so.

Mr. Malcolm pointed out that the Government provided a water supply for certain districts at the request of the people concerned, and on the understanding that each district should bear the cost of its own particular scheme. If the Government could see their way to nationalise the whole of the water schemes it would be a different matter.

Mr. Greig (Port Pirie) said a good supply of water was needed to grow lucerne. The question as to which was the best, a petrol or an oil engine, was a very debatable one. The matter had been discussed at a meeting of the Port Pirie Branch, and a substantial majority favored the petrol engine for all farming purposes, pumping included. In his opinion it was a decided mistake to use sprinklers for irrigation purposes when the quality of the water was not up to standard. Many plants suffered if mineralised water was thrown on their foliage. He thought if there was any doubt as to the quality of the water, those proposing to use sprinklers should, before doing so have the water analysed. He intended having that done, but when he found it would cost him £3 or £4 it was a different matter.

Mr. G. G. Nicholls pointed out that the Director of Agriculture was prepared to have samples of water sent in by producers analysed free of cost. That was, of course, providing the reasons given for desiring the analysis were deemed satisfactory.

Mr. S. O. Smith (Angaston) said he had used sprinklers for watering lucerne day and night in hot weather. By the use of sprinklers the water could be better distributed than was the case with trenches. There was no doubt windmills were the cheapest means of pumping water.

The motion was put to the meeting as follows:—"That the Advisory Board be requested to bring under the notice of the Government the difference in the prices charged for water from the Beetaloo and Bundaleer reservoirs and from the Barossa and Happy Valley schemes, and to ask the Government to adjust the difference."

The resolution was declared lost by a substantial majority.

THE EVENING SESSION.

The Congress was continued in the evening, when a large number of delegates and visitors attended. The Chairman of the Advisory Board (Mr G. R. Laffer) presided.

THE SHEEP-CARRYING CAPACITY OF A LOWER NORTH FARM: A RECORD OF SEVEN YEARS' WORK.

Professor A. J. Perkins (Principal Roseworthy Agricultural College) read the following paper on "The Sheep-carrying Capacity of a Lower North Farm: A Record of Seven Years' Work":—

INTRODUCTORY.

In 1907 and 1908 I published data relating to the number of sheep we had carried during those two years on the Roseworthy Agricultural College Farm. I could not pretend, however, that the figures given at the time were sufficiently far-reaching to give them anything like the value of fair averages. Since then I have set myself the task of attaining this object, and to-day, with the record of seven years' work before me, I feel justified in claiming that the figures that I propose giving you correspond very fairly to our general average conditions. During these seven years a careful record of the individual sheep-carrying capacity of each field has been kept; this involves an amount of tedious work that only those who have had to carry it out can appreciate; and I wish, in this connection, to express my indebtedness to Mr. J. P. Richardson, late Farm Manager of the College Farm, for the conscientious and painstaking manner in which he has kept these records for a period of seven years. I am also indebted to Mr. A. J. Adams, M.A., for checking the numerous calculations which form the foundation of this paper.

DEFINITION OF THE LOCALITY.

It will be noticed that I have called our records the records of a Lower North farm; strictly speaking, however, from the point of view of the statistician, we do not belong to the Lower North. I incline, nevertheless, to the opinion that our conditions, both of soil and climate, approximate very closely to the average conditions of the Lower North. We are not a particularly favored locality, nor, on the other hand, are we a particularly disinherited one; and I feel justified in believing that what can be done by us in the way of live stock carrying can be equalled, if not improved upon, over the bulk of the Lower North. Portion of our land is characteristic limestone mallee land, typical of Yorke's Peninsula; portion of it is heavier in character and represented by Murray box and peppermint flats; native pine sand ridges run through part of the farm, and to a limited extent some of the fields are of recent lacustrine formation. On the whole, under natural conditions, this land can never have had a very high sheep-carrying capacity. I hope to show that cropping and tillage generally has done much towards improving it in this direction.

THE SEVEN SEASONS.

The value of pasture, and its sheep-carrying capacity, is so dependent on the rainfall and its general distribution throughout the year, that I deem it essential to indicate at the outset details concerning it in Table I.

TABLE I.—*Showing* 1906-12 *Rainfall Comparatively with the Means of* 30 *Years*—1883-1912.

								Means.	
	1906.	1907.	1908.	1909.	1910.	1911.	1912.	1906-12.	1883-1912.
January	—	0·05	0·48	0·75	1·72	—	0·09	0·30	0·86
February	0·08	0·33	0·43	0·28	—	2·13	0·21	0·49	0·50
March	2·64	0·17	1·09	1·17	4·43	0·66	0·70	1·55	0·88
April	0·45	2·79	0·76	1·91	0·23	0·33	0·91	1·05	1·74
May	0·99	1·96	3·36	2·89	3·20	1·79	0·19	2·05	1·80
June	2·84	1·57	2·89	1·84	2·81	2·33	1·68	2·28	2·65
July	1·99	1·15	1·42	3·80	2·86	1·56	1·87	2·09	1·91
August	3·35	2·18	1·79	4·56	1·32	0·68	3·19	2·44	2·09
September	2·65	1·08	3·09	1·62	2·64	2·36	2·43	2·25	1·79
October	1·77	1·22	2·15	2·55	2·55	0·37	0·94	1·65	1·60
November	2·26	1·86	0·07	2·08	1·18	0·04	1·84	1·33	1·04
December	0·70	0·62	0·21	0·70	0·93	1·44	0·92	0·79	0·87
Total	19·72	15·05	17·74	23·05	23·87	13·69	14·97	18·29	17·66

We may note that this period of seven years included three years in which the rainfall was above the average—1906, 1909, and 1910; one season in which it was about normal—1908; and three seasons in which it was below the average—1907, 1911, and 1912. The average rainfall for the seven years —1906-12—was slightly above the recorded average of thirty years—1883-1912. On the whole, therefore, in so far as our records go, this period of seven years may be taken to be fairly representative of our normal average conditions.

AVERAGE NUMBER OF SHEEP CARRIED BY THE ROSEWORTHY AGRICULTURAL COLLEGE FARM DURING 1906-1912.

We may now consider the number of sheep that were carried by the College Farm over this period. These are indicated below, month by month, in Table II.

Table II.—*Showing Number of Sheep carried by the Roseworthy Agricultural College Farm between* 1906-7 *and* 1912-13.

Months	1906 7	1907 8	1908 9.	1909 10	1910 11	1911-12	1912 13	Means
April	865	1,181	1,253	1,282	1,108	1,197	1,081	1,138
May	824	1,148	1,328	1,425	1,218	1,383	1,258	1,226
June	1,211	1,603	1,551	1,662	1,516	1,722	1,392	1,522
July	1 173	1,629	1,763	1,735	1,712	1,899	1,460	1,624
August	1,158	1,610	1,774	1,644	1,713	1,870	1,530	1,614
September	1,154	1,613	1,790	1,553	1,679	1,728	1,518	1,577
October	1,111	1 370	1,638	1,513	1,466	1,519	1,419	1,434
November	1,616	1,261	1,458	1,459	1,236	1,326	1,231	1,370
December	1,635	1,239	1,359	1,374	1 183	1,218	1,089	1,300
January	1,550	1,225	1,299	1,249	1 172	1,138	1,041	1,239
February	1,464	1,254	1,289	1,172	1 182	1,073	1,027	1,209
March	1,374	1,256	1,297	1,141	1 197	1,047	1,000	1,187
The season	1,261	1 366	1 483	1,434	1 365	1,427	1,254	1,370

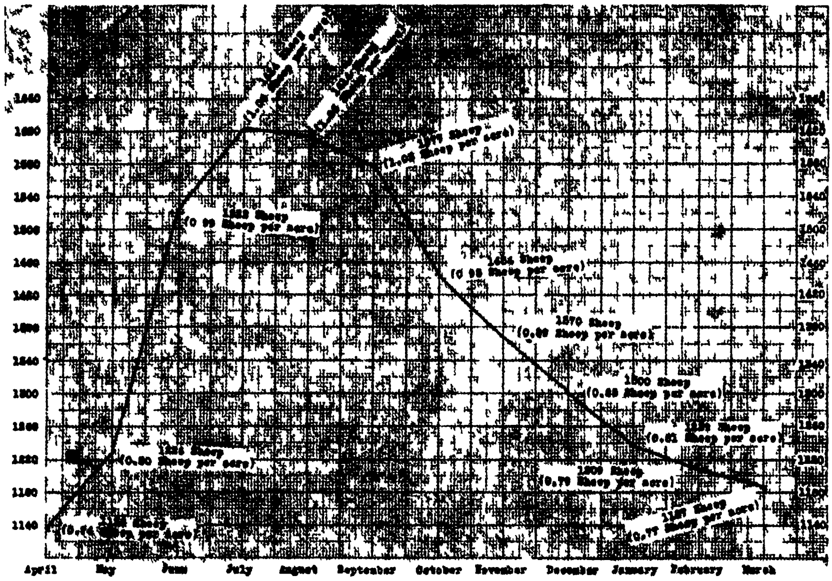

Fig 1 Illustrating Table II and showing the Average Number of Sheep carried month by month on the College Farm, (1906-1913) together with their relation (Sheep per acre) to the total farm arable and grazing area.

In Fig 1 is given a graphic illustration of the last column in Table II, in which is indicated the mean number of sheep carried by the College Farm in each month of the year between 1906 and 1913 It will be noted how the curve starts low in April, before the ewes have lambed , how it rises slightly in May, with the tailing of the Merino lambs , how it rushes up in June, when the bulk of the cross-bred lambs are tailed , how it reaches a maximum in July, with the tailing of the late-dropped lambs , how it remains stationary in

August, except for occasional deaths or sales; begins to fall in September, with the first sales of fat lambs; and subsequently continues to fall evenly through the balance of the season as fat lambs are sold, or aged ewes culled.

We may note, too, that between 1906 and 1913 the average number of sheep grazed on the College Farm throughout the year was represented by 1.370.

THE CHARACTER OF THE FLOCK.

I suppose that at this stage it is more or less essential that I should say something on the general character of the flock we have kept. I have already referred to fat lambs; and whilst, perhaps, in a sense they represent the business part of our flock, I cannot for an instant pretend that our flock has been a typical fat lamb flock; very far from it. I am quite prepared to admit that our flock would prove more profitable if we were to confine ourselves to the rearing of fat lambs; but, in an educational institution, there are other things to think of besides the profit and loss of field operations. And it is these other things that have led to the building up on the College Farm of a very heterogeneous flock. In the first place, under our conditions, I am firmly convinced that we cannot improve upon the cross-bred ewe as a mother for fat lambs: but which type of cross-bred ewe is best? This, no doubt, is a question the solution of which must vary with localities; it had not been solved for us, and within recent years we have tested on the College Farm half-bred Leicesters, half-bred Romney Marshes, half-bred Dorset Horns, half-bred Shropshires, and half-bred Southdowns. It will be realised, therefore, that our flock of cross-bred ewes has been a very mixed one. But, in addition to rearing fat lambs from cross-bred ewes, we have always bred the ewes themselves. This has meant the presence on the farm of a flock of pure-bred Merino sheep; and, further, with few exceptions, we have always bred our own Merino ewes; and, more, we have also bred our own Merino rams. Finally, since I have always been of the opinion that the best possible sire for fat lambs of cross-bred ewes is the Southdown ram, and good Southdowns are not easily obtainable in South Australia, we have kept a small stud flock of pure Southdown sheep, from which we have bred all the rams we have required.

I am not holding up our flock as an example worthy of being followed by farmers generally; I merely wish to point out that the circumstances of an educational institution will always tend to lower the profit-earning power of any flock that may be kept.

OTHER FORMS OF LIVE STOCK DEPASTURED.

In Table II. I have indicated the number of sheep grazing on the College Farm. It must not be overlooked, however, that sheep are not the only form of livestock that have access to our pastures. We keep a dairy herd, milking according to circumstances from 25 to 30 cows; and since we rear our own cows the farm always carries a varying number of young heifers and calves. Our working horses, too, from time to time find their way into the grazing fields; and, additionally, since we rear draught horses, grazing fields are open to the colts and fillies as much as circumstances permit of. The extent to which these large stock—cattle and horses—are depastured, and not hand fed, depends of course much on circumstances; and although, as we shall see later on, grazing as distinct from hand-feeding is easily traceable where individual fields are concerned, it is not so easily estimated in the aggregate. In this connection, therefore, I shall have to content myself with a statement of the number of horses and cattle present on the farm in September of each year, and the additional remark that these larger form of live stock—each head of which has an average grazing equivalent of five sheep—have occasional access to our grazing areas.* These data are summarised below in Table III.

TABLE III.—*Showing Number of Horses and Cattle Present on the College Farm in September of Each Year,* 1906-12, *together with their Calculated Grazing Equivalent as Sheep.*

	1906.	1907.	1908.	1909.	1910.	1911.	1912.	Means.	Grazing Equivalent as Sheep.
Horses	35	50	54	55	63	70	76	58	290
Cattle	74	69	59	68	72	64	52	65	325
									615

I make no reference to pigs, since for grazing purposes the latter have access to only a very limited area of the farm fields.

GENERAL DISTRIBUTION OF THE FARM AREA.

Before determining the grazing area that has through this period of seven years been open to our flock, it will be as well to consider what has been the general distribution of the arable farm land over the same period. It should be stated here that the general farm area has between 1906 and 1913 been extended by two successive purchases of adjoining fields that came into the market. In Table IV. I have indicated the general distribution of our farm area between 1906 and 1913. No account has been taken in this table of roads, plantations, buildings, &c., which cannot be taken as available for grazing purposes.

TABLE IV.—*Showing General Distribution of Farm Arable and Grazing Area*— 1906–13.

	1906-7. Acres.	1907-8. Acres.	1908-9. Acres.	1909-10. Acres.	1910-11. Acres.	1911-12. Acres.	1912-13. Acres.	Means. Acres.
Rape	51·5	44·4	38·0	36·5	20·0	23·0	—	—
Kale	20·0	30·3	—	23·0	3·5	4·7	—	—
Crimson clover	22·3	—	—	—	—	—	—	—
Maize	4·7	—	—	—	10·0	—	—	—
Sorghum	—	20·0	22·3	37·5	22·3	36·8	19·2	—
Turnips	—	6·5	23·7	—	—	—	—	—
Peas	—	—	23·0	20·0	—	—	22·3	—
White mustard	—	—	15·5	—	—	—	—	—
Sown grasses	—	—	12·0	32·0	32·0	32·0	12·0	—
Lucerne	—	—	—	—	85·0	119·0	119·0	—
Total grazing crops	98·5	101·2	134·5	149·0	172·8	215·5	172·5	149·1
Ordinary Pasture	272·0	393·5	262·2	429·4	299·5	281·5	247·5	312·2
Total area available for grazing	370·5	494·7	396·7	578·4	472·3	497·0	420·0	461·3
Under crop (mostly cereals)	634·0	447·4	542·6	620·4	611·4	611·8	726·0	599·1
Bare fallow	380·7	443·1	445·9	411·9	526·0	500·2	609·0	473·8
Total arable and grazeable area	1,385·2	1,385·2	1,385·2	1,610·7	1,609·7	1,609·0	1,755·0	1,534·2

Thus, then, between 1906 and 1913 the average extent of the arable and grazing farm area has been 1,534·2 acres; during the same period the average area under crop in each year has been 599·1 acres, the average area under grazing crops has been 149·1 acres, the average area of fields lying out (ordinary pasture) has been 312·2 acres, and the average area treated as bare fallow has been 473·8 acres.

RELATION OF NUMBER OF SHEEP KEPT TO TOTAL ARABLE AND GRAZING AREA OF THE COLLEGE FARM.

A reference to Table II. will show that between 1906 and 1913 the College Farm carried a yearly average of 1,370 sheep. If we connect this number with the average arable and grazing area of the farm over the same period, we shall see that this represents 0·89 sheep to the acre, or close on nine-tenths of a sheep for the whole area throughout the year. If, further, we bear in mind that, in addition to sheep, both cattle and horses have had access to the same grazing area, we shall not be far out in the statement that a farm 1,534·2 acres in area, in which 1,072·9 acres have been under cereals or treated as bare fallow—over 70 per cent. of the total area—has carried between 1906 and 1913 an average of one sheep to the acre.

The average grazing area available over the same period is shown to be 461·3 acres in Table IV.; and this works out to 2·97 sheep to the acre. This figure, however, as we shall have occasion to see, is misleading: it does not take into account the grazing value of the stubbles, nor of the fallowed fields before they are broken up, nor of the bare fallow itself.

A reference to Fig. 1 will show how the average relation of sheep kept to the total arable and grazing area of the farm has varied from month to month.

HAND-FEEDING.

The question will immediately be raised as to the extent to which, under the conditions indicated, sheep will need, independently of grazing crops raised, to be hand-fed. I may say that I have never taken the view that in the absence of natural feed the flock must be allowed to starve; and we all know that at such times, except at considerable sacrifice, it cannot, as a rule, be sold; hence the only alternative is artificial feeding until grass shall have become available. I may say that in our district in years in which April and May rains are abundant, no hand-feeding at all is necessary. Such was our experience in 1907-8, 1909-10, and 1910-11. Seasons 1906-7, 1908-9, and 1911-12 were not on the whole quite as favorable to grazing; and during the months of April and May our various flocks were kept going with the residues of the preceding harvests, represented for the most part by cocky chaff and cavings or broken straw—to the latter a certain amount of molasses was usually added. This, however, represents very moderate hand-feeding, and in ordinary circumstances is all that is as a rule needed. Our period of seven years, however, includes 1912-13: a season, I think, in which we had a very good example of how far hand-feeding must needs go in extreme cases, and I regret to think that this example bids fair to be bettered in the present season. In the circumstances it will be interesting to indicate in detail what was actually fed out to sheep, with its actual cost. These details are shown below in Table V.

TABLE V.—*Showing Amount and Value of Foodstuffs Fed Out to Sheep in* 1912–13.

	Bran	Crushed Corn.	Pollard.	Hay Chaff.			Straw Chaff.			Baled Straw.	Molasses
	Bush.	Lbs.	Bush.	T.	C.	L.	T.	C.	L.	Cwts.	Cwts.
April..........	—	—	—	0	16	86		—		15	—
May	633	3,380	—	0	10	0	0	6	0	—	5
June	1,059	—	—		—		9	1	0	—	—
July	630	1,656	24	2	4	0	9	19	0	—	—
August	336	438	—	0	15	0	0	9	0	—	—
September ...	—	76	—		—			—		—	—
November ...	6	—	—	0	1	0		—		—	—
December	12	—	—	0	2	0		—		—	—
January	12	—	—	1	0	0		—		—	—
February	42	—	—	4	7	36		—		—	—
March.........	36	—	—	2	1	0		—		—	—
Totals......	2,766	5,550	24	11	17	10	19	15	0	15	5
Values	£184/8/-	£11/11/3	£1/15/-	£29/12/8			£49/7/6			£1/6/-	£1/-/-

Total value of foodstuffs.................. £279/0/5

Thus, then, in a season exceptionally unfavorable to grazing, we were compelled to supply our sheep with hand-fed foodstuffs to the value of £279 0s. 5d. The average number of sheep carried by us throughout that season amounted to 1,254. If the cost of the hand-fed foodstuffs be distributed over this number of sheep it works out to 4s. 5d. a head, a sum which is by no means crippling even in a bad season. In the same season the gross receipts from the flock were represented by £960 13s. 4d., or 15s. 4d. per head of sheep kept; and after deduction of the cost of hand-feeding there is ample margin for ordinary expenses coupled with a reasonable profit.

ON THE CLASS OF PASTURE OPEN TO SHEEP ON THE AVERAGE LOWER NORTH FARM.

I shall now proceed to examine in detail the carrying capacity of the various forms of pasturage open to sheep on Lower North farms. The pasturage usually available may be classified under the following headings :—

1. Ordinary pasture, or fields temporarily out of cultivation.
2. Stubble pasture.
3. Bare fallow grazing.
4. The feeding-off of crops.
5. Grazing forage crops.

ORDINARY PASTURE.

I have called ordinary pasture the kind of pasture offered by plants growing spontaneously in fields temporarily left out of cultivation, and pasture of exceptional value it has proved since the general use of phosphatic manures for wheat. In Table IV. I have shown the mean area under ordinary pasture to have been represented by 312·2 acres over our period of seven years. I have also stated that this figure is misleading since it takes into account only those fields which happen to have been left out of cultivation for the season. In addition to these fields there are also the fields which are being fallowed in the same season, and which for portion of the year, at all events, are available for grazing purposes. To what extent this is the case will be seen below in Table VI., in which are indicated the areas of ordinary pasture available in each month of the year over the whole period of seven years, together with the general means.

Table VI.—*Showing Areas Available as Ordinary Pasture in Each Month of the Year between* 1906 *and* 1913.

	1906-7. Acres.	1907-8. Acres.	1908-9. Acres.	1909-10. Acres.	1910-11. Acres.	1911-12. Acres.	1912-13. Acres.	Means. Acres.
April......	652·7	836·6	723·6	913·8	892·8	853·9	851·0	817·8
May	652·7	836·6	723·6	913·8	892·8	853·9	851·0	817·8
June	641·2	832·3	719·1	895·5	892·7	836·3	827·9	806·4
July	519·4	726·9	594·3	758·7	733·3	666·3	614·0	659·0
August ...	404·6	601·3	487·1	680·5	591·3	507·8	439·1	530·2
September	306·6	499·1	379·6	547·0	524·5	381·6	294·5	419·0
October ...	272·0	411·6	285·4	456·3	458·3	306·7	247·5	348·3
November .	272·0	393·5	262·2	429·4	419·5	291·7	247·5	330·8
December .	272·0	393·5	262·2	429·4	419·5	281·8	247·5	329·4
January ..	272·0	393·5	262·2	429·4	419·5	281·5	247·5	329·4
February .	272·0	393·5	262·2	429·4	368·5	281·5	247·5	322·1
March.....	272·0	393·5	262·2	429·4	334·5	281·5	247·5	317·2
Yearly means	400·8	559·3	435·3	609·4	578·9	485·4	446·9	502·3

From Table VI. it will be seen that the average area available as ordinary pasture instead of being 312·2 acres was over the seven-yeaŧ period 502·3 acres. I have given the last column of this table graphic illustration in Fig. 2. The fall of the curve illustrates graphically the gradual reduction of the area available for ordinary pasture as the season advances. In April and May—the seeding months—the ordinary pasture is at its maximum. In June, in which late seeding operations are still in hand, the reduction of the area, as a result of early fallowing operations, is only slight. In July,

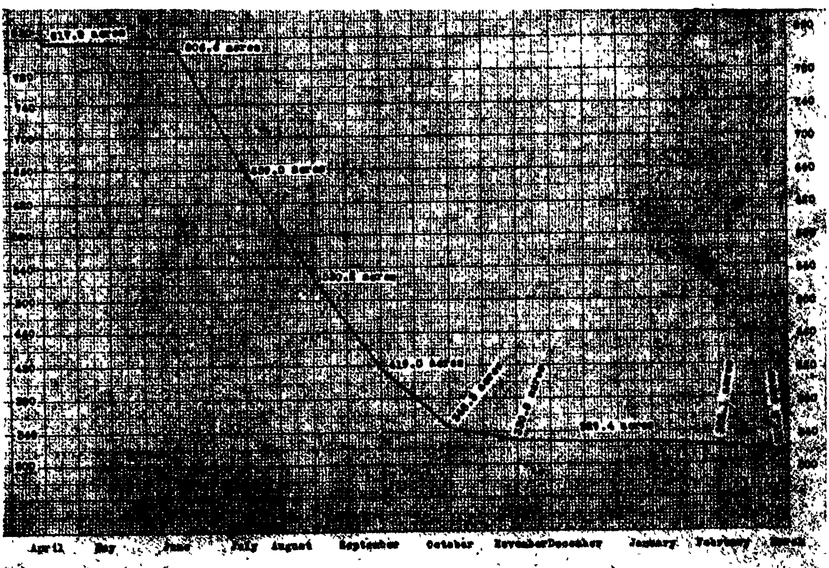

Fig 2. Showing gradual decline of Available Ordinary Pasture area with the progress of Fallowing Operations 1906-13.

when fallowing operations are in full swing, the decline is very rapid, and equally pronounced in August and September. In October late fallowing continues, and there is a further reduction in the area available for grazing, but less pronounced than was the case in the preceding three months. From November to March the area available for grazing purposes remains practically stationary, with the exception of limited areas that may occasionally be broken up towards the end of the season should heavy thunderstorms prepare the way.

THE SHEEP-CARRYING CAPACITY OF ORDINARY PASTURE.

We may now proceed to examine what our records show to have been the average sheep-carrying capacity of ordinary pasture over this period of seven years. There are two observations that I wish first to make in this connection. In giving the sheep-carrying capacity of ordinary pasture for any given year, all fields of which we have accurate records are taken into consideration ; in almost every year, however, a few fields are not taken into our calculations, either because the records concerning them were not accurately kept, or because for various reasons it was not possible to keep them. Secondly, in the figures given herewith, *livestock that were not artificially fed* only are taken into account ; for the most part they consisted of sheep ; occasionally, however, cattle or horses were recorded as grazing with them ; in the latter case, the larger heads of livestock have been reckoned in my tables as being equivalent to five sheep, which is, if anything, below their grazing value. These remarks that have been made for ordinary pasture apply equally to all other forms of grazing, with which we shall have to deal in the sequel, and will not, therefore, be repeated.

Details concerning the sheep-carrying capacity of ordinary pasture from month to month over the period extending between 1906 and 1913 are shown below in Table VII.

TABLE VII.—*Showing Sheep-Carrying Capacity, Month by Month, on Ordinary Pasture at the Roseworthy Agricultural College Farm*, 1906-13.

Table VII. shows the average sheep-carrying capacity of ordinary pasture to have been represented by a little over one and a half sheep to the acre over a period of seven years (1906-13). It will be noted that 1912-13 is the only season in which it was below a sheep to the acre; and this is accounted for by the fact that in the opening four months of the season the carrying capacity of ordinary pasture was practically nil.

I have given graphic illustration to the last column in Table VII., in Fig. 3; the curve shows how the carrying capacity opens low, gradually ascending with every succeeding month until a maximum is attained in September; thereafter, in October and November, there is a slight decline in the carrying capacity of the fields; a decline which is far more marked towards the end of the season, when, fortunately for the farmer, the cereal stubbles become available for grazing purposes.

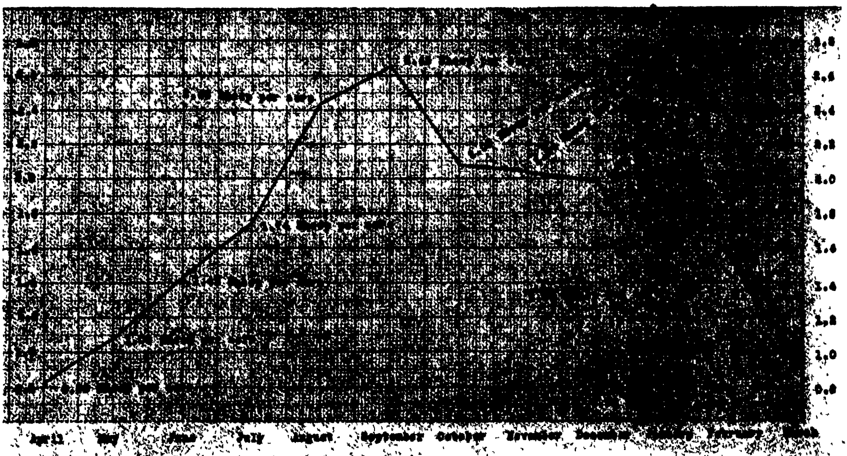

Fig. 3. Showing Average Number of Sheep to the acre carried by Ordinary Pasture on the College Farm 1906-1913.

STUBBLE-GRAZING.

In the summer months, so soon as the hay has been stacked and the corn garnered, the stubble fields offer valuable grazing to the farmer who owns sheep; and it frequently happens—when earlier circumstances have led to the heavy stocking of other fields—that access to these fields is anxiously awaited. The character and value of the feed available must vary according as the crops have been cut for hay, or harvested at maturity with the complete harvester, or merely stripped. It may perhaps be thought that hayfields can offer but little that is of value to a flock of sheep; experience shows, however, that is very far from being the case. The figures that I shall have occasion to quote—the results of our own experience—refer almost exclusively to fields in which the crop has been cut down with the binder. We make but little use of either stripper or complete harvester; we bind our grain crops and thresh them out at leisure; for us straw is too valuable an asset to be burnt or trod under foot. It will be quite evident, therefore, that the average farmer's harvester-reaped stubbles will be infinitely superior as grazing grounds to our own; the scattered grain, the chaff, the straw, will represent so much feeding material in which the College stubbles are lacking, or which they hold only to a very limited degree. These facts, notwithstanding, we have always, as I shall have occasion to show, found our stubble-fields grazing grounds of exceptional value.

There is an indirect benefit which attaches to the consistent grazing of stubbles which cannot be too strongly insisted upon; I refer to the ready mastery which it gives the farmer over "stinkwort" (*Inula graveolens*). I think I can say, without offensive boastfulness, that in the matter of stinkwort, the College fields are in marked contrast with those of most of our neighbours; and this I attribute exclusively to the fact that every year we graze our stubbles heavily and consistently with sheep as early in the season as possible. For the purpose it is of very little use waiting until March to turn the sheep into the stubbles; they must have access to them whilst the weed is still in the early stages of its growth; young plants sheep will eat out completely; of older ones they will no more than nibble off the growing extremities. If a field is known to be badly infested with stinkwort it should be heavily stocked with sheep as soon as it is clear of the harvest workers; it is the only method that I know of that will effectively keep the pest in check.

The figures given below in Table VIII. give the sheep-carrying capacity of stubble-fields—not for a whole year, but for a period extending from December to March, inclusively (122 days)—during which the stubbles may be said to be available for grazing purposes.

TABLE VIII.—*Showing the Sheep-Carrying Capacity of Stubble-Fields from December to March, inclusively* (122 *Days*), 1906-13.

Season.	Sheep per Acre. (Dec.-March).
1906-7	1·53
1907-8	2·88
1908-9	1·11
1909-10	1·26
1910-11	1·60
1911-12	1·66
1912-13	0·86
Mean 1906-13	1·55

Thus, then, over a period of seven years, our stubbles have carried an average of a little over one and a half sheep to the acre from December to March, inclusively.

FALLOW-GRAZING.

Fallow-grazing fills a double purpose on the farm; on the one hand it serves to clean the fallows, both effectively and expeditiously, and on the other it supplies new grazing grounds at a time of the year when the ordinary pasture area is fast tending towards its minimum. I am aware that the practice is not in the best interests of the general quality of the fleeces; but the slight depreciation in the wool that it unavoidably brings with it cannot possibly outweigh its great advantages to the farmer. Moreover, the grazing of sown and cultivated forage crops is open to very much the same sort of objection; and I do not suppose that anybody is seriously prepared to maintain that the farmer should refrain from taking advantage of them. The fact is that the farmer's wool must always continue to be described as "shabby," relatively to that of the stationowner, whose sheep graze over cleaner and firmer pastures. On the other hand, on the farm the carcass is the chief consideration, and wool only secondary; whilst the reverse is the case on station property.

The extent to which farm fallows offer grazing facilities depends much on the nature of the season, and the effectiveness with which the fallows have been tilled. I indicate below, in Table IX., what has been our experience in this direction between 1906 and 1913.

TABLE IX.—*Showing the Grazing Capacity of the College Farm Fallows, 1906-13.*

	1906-7.	1907-8.	1908-9.	1909-10.	1910-11.	1911-12.	1912-13.	Means.

July	—	—	—	—	—	—	—	—
August ...	—	—	—	—	—	0·08	0·07	0·02
September	0·07	0·78	0·80	0·21	1·14	0·44	0·25	0·53
October ...	1·72	0·10	0·21	0·60	3·01	0·65	0 64	0·99
November	2·57	0·02	0·04	1·17	1·97	0·01	0·57	0·91
December .	0·27	0·01	0·31	0·53	—	—	0·14	0·18
January ..	—	0·18	0·09	0·08	0·23	—	0·03	0·09
February .	—	—	0·04	0·16	0·44	—	—	0·09
March.....	—	—	—	—	0·19	—	0·06	0·04
Sep-.Dec. (122 days)	1·16	0·23	0·34	0·63	1·53	0·29	0·42	0·66
Jan.-March (90 days)	—	0·06	0·04	0·08	0·28	—	0·03	0·07
April-May (61 days)	0·15	—	—	0·36	—	—	0·11	0·09

It will be noted that the normal grazing time for bare fallows extends from September to December, inclusively; for that period of 122 days the College

Farm fallows averaged about two-thirds of a sheep to the acre between 1906 and 1913. The grazing available in the January-March period is on the whole insignificant, being represented by 0·07 sheep per acre for the period under consideration. The grazing which may take place before seeding operations, under favor of early rains, is also equally insignificant, being represented by 0·09 of a sheep per acre.

THE FEEDING-OFF OF CEREAL CROPS.

I shall have but little to say to-day on the feeding-off of cereal crops with sheep. Quite recently, in conjunction with Mr. Spafford, I had occasion to publish a long report embodying our general conclusions, based on some experimental work we had carried out on the subject. I shall, therefore, content myself with remarking here that in my view, the feeding off of cereal crops with sheep must always remain on any farm of more or less accidental occurrence. It must be evident that these crops have not been put in for the special benefit of the flock; and, if they are fed off at all, it is only when they stand manifestly in need of it and appear likely to benefit in yield by the treatment. And this can be the case only in exceptional circumstances and seasons; when the crops have been sown early in years of abundant April rains; when seeding has been too thick, or too thin; when the land is in too high condition, and growth correspondingly rank, &c. All these are more or less exceptional cases; and adequately to meet them it is always of advantage to have a flock handy. It is then the function of the sheep to save or improve the crop; but I cannot agree with those who argue, knowingly or unknowingly, that the crops are there to save the flock.

GRAZING FORAGE CROPS.

Finally, on any farm on which sheep are kept, portion of the farm area should always be sown to suitable kinds of forage crops that can be grazed. These crops will naturally vary with circumstances and districts; I must, however, confine my remarks to those crops that were tested on the College Farm over our period of seven years. These include rape, kale, crimson clover, maize, sorghum, turnips, peas, white mustard, sown grasses, and lucerne.

RAPE.

The great value of rape as a sheep forage crop, adapting itself well to our average conditions of climate, cannot be over-stated. During recent years we have made very free use of rape on the College Farm, and have found it, as a rule, invaluable between June and January. I have indicated below in Table X, what has proved the sheep-carrying capacity of this crop in each month of the period of seven years extending between 1906 and 1913.

TABLE X.—*Showing the Sheep-Carrying Capacity of Rape on the College Farm, Month by Month, between* 1906 *and* 1913.

	1906-7.	1907-8.	1909-10.	1910-11.	1911-12.	Means.
	Sheep per Acre.					
April	Nil	Nil	Nil	Nil	Nil	—
May	Nil	0·54	Nil	Nil	Nil	0·11
June	2·22	2·25	2·57	Nil	Nil	1·41
July	2·83	1·46	Nil	Nil	Nil	0·86
August	3·51	3·11	Nil	7·30	1·29	3·04
September	5·80	2·63	6·49	0·97	2·62	3·70
October	5·29	3·78	0·84	5·81	1·41	3·43
November	2·17	1·65	Nil	5·43	2·24	2·30
December	2·47	0·89	2·46	10·89	1·25	3·59
January	2·06	Nil	0·52	10·44	Nil	2·60
February	Nil	Nil	0·10	Nil	Nil	0·02
March	Nil	1·78	0·29	1·73	1·75	1·11
The 12 months	2·22	1·51	1·10	3·60	0·88	1·86
June-January period (eight months)						2·79

We see, then, that the grazing value of rape, grown mainly as a catch crop and on very slight tillage, was represented for the whole 12 months by a sheep-carrying capacity of 1·86 sheep to the acre; or, if we take the eight months during which it is more or less available on the College Farm—June-January—a sheep-carrying capacity of a little over two and three-quarters sheep to the acre. It may be added that did other farming operations permit of more efficient tillage being given to rape it would undoubtedly show up to better advantage than appears to be the case in the average data of Table X.

KALE.

The variety of kale known as "Thousand-headed" is the variety that we have almost invariably made use of for sheep-feeding purposes. Data concerning the sheep-carrying capacity of this crop are shown below in Table XI.

TABLE XI.—*Showing the Sheep-Carrying Capacity of Thousand-Headed Kale on the College Farm, Month by Month*— 1906–1913.

	1906-7.	1907-8.	1908-9.	1909-10.	1910-11	Means
	Sheep per Acre.					
April	—	—	—	—	—	—
May	—	—	—	—	—	—
June	—	—	—	—	—	—

March	—	—	—	—	—	—
Twelve months	3·81	1·32	1·70	2·86	2·63	2·46
September-January period (five months)						5·87

Table XI. shows the sheep-carrying capacity of kale to have proved equivalent to about two and a half sheep to the acre for a period of 12 months ; or, if we reduce this to the period during which the crop was actually available to us—September–January—equivalent to 5·87 sheep to the acre for a period of five months.

I am, of course, aware that under special treatment kale may still be available for grazing purposes in the early autumn months of the following season, immediately after the first rains. As a rule, however, this practice has not proved particularly advantageous to us, and we generally look upon kale as a valuable forage crop supplying an abundance of succulent feed in the late spring and over the greater part of the summer.

TURNIPS.

We have never grown turnips for sheep to any very large extent, and this chiefly because under our conditions of climate it is possible to grow them to any advantage only when autumn sown. They grow very rapidly, but unfortunately run up to seed on the first approach of warm weather, with the result that they are very largely wasted unless rapidly fed down at a time of year when other feed is generally available in large quantities. There is no doubt that even autumn-sown turnips supply enormous quantities of sheep feed ; it is secured, however, at a cost which is generally in excess of the expenditure involved in the raising of other types of forage crops. Hence I adhere to the opinion that for our district turnips cannot have the value that attaches to them in those districts in which they are usually spring sown and autumn or winter fed.

Data bearing on the results secured by us within recent years are shown below in Table XII.

TABLE XII.—*Showing the Sheep-Carrying Capacity of Turnips on the College Farm, Month by Month* –1907–13.

	1907-8.	1908-9.	1909-10.	1910-11.	1911-12.	1912-13.	Means.
	Sheep per Acre.						
April	—	—	—	—	—	—	—

Twelve months	2·26	1·84	3·46	3·15	1·92	1·99	2·43
September-December period (122 days)							7·27

We find, therefore, that for a period of 12 months the sheep-carrying capacity of turnips averaged out at close on two and a half sheep to the acre; or, if we reduce these figures to the September-December period (122 days), to over seven and a quarter sheep to the acre. The value, therefore, of turnips as a forage crop cannot be denied, even when autumn sown. The area sown to turnips, however, should, under our conditions, be confined to what may prove useful towards the spelling of other grazing areas in the spring.

VETCHES.

No more than turnips have we grown vetches for grazing purposes to any great extent; their value in this direction, and also as nitrogen providers is, no doubt, great. The chief obstacle to the more extended use of vetches in ordinary farming operations appears to me, for the present at all events, to be the exorbitant price charged for seed. Our data on the grazing value of vetches are summarised below in Table XIII.

TABLE XIII.—*Showing the Sheep-Carrying Capacity of Vetches on the College Farm, Month by Month* -1908-12.

	Sheep per Acre.			
	1908-9.	1910-11.	1911-12.	Means.
April	—	—	—	—
May	—	—	—	—
June	—	—	—	—
July	—	—	—	—
August	—	—	—	—
September	10·95	Nil	18·04	9·66
October	10·95	Nil	6·55	5·83
November	Nil	24·66	Nil	8·22

February	—	—	—	—
March	—	—	—	—
Twelve months	1·83	2·88	2·05	2·25
September-December period (122 days)				6·74

In the limited tests to which we put them vetches show a grazing value about equal to that of turnips. To their advantage, however, it may be said that whilst autumn-sown turnips must be fed off in the spring, a well-grown crop of vetches may be left untouched until required.

PEAS.

Peas have within recent years had a good deal of attention drawn to them. As a crop raised for seed, however, I do not anticipate that they are likely to make much progress in our midst; not, at all events, in our relatively drier districts. They present too many harvesting difficulties under dry conditions of climate to make of them a popular grain crop. For forage purposes, on the other hand, peas may be looked upon as invaluable in all soils that are light or, at all events, of not more than average consistency. Among the advantages that attach to this crop it may be mentioned that, like vetches, although not perhaps to an equal degree, they are nitrogen collectors, and as such they help to raise the natural fertility of the land on which they are grown. Another great advantage is the short growing period of peas, which for forage purposes makes it more or less immaterial whether they are early or late sown. Early seeding—April or May—results as a rule in heavy haulm growth and comparatively light podding; and this because the plants will come into bloom at a time when sharp frosts are still rife. Late seeding July or August according to districts—will give more abundant and better filled pods, but less luxuriant haulm growth. To the credit of early seeding it may be added that if the peas are fed off sufficiently early, and weather conditions are favorable, they will give rise to a very satisfactory grazing aftermath. As a crop that must fit in with our more important cereal crops, peas have often given me cause for reflection. In most countries both practice and theory agree that the pea crop should prepare the way for the wheat crop, and should therefore immediately precede it. Hence peas have come to be looked upon as a winter-grown fallow crop; and for the purpose they are admirable so long as the weeds that grow luxuriantly in their midst can be prevented from going to seed. There are only two ways of realising this object: early feeding-off of the crop, or having recourse to far more labor and tillage than we can well afford to do. If the crop is fed off early we lose the advantage of holding the pea crop over until other sources of feed are on the wane. I have come to the conclusion therefore and I recognise that others had come to it before me—that with us peas should not be treated as a fallow crop, but should be sown on a cereal stubble, broken up as well as circumstances permit of in the early autumn. In the circumstances it will matter little if the pea crop is dirty, and this will certainly be the case. It can be fed down at whatever time of the year is found most convenient for the purpose, and in the following year the land should be treated as bare fallow, during the course of which will take place the nitrification of the organic nitrogen left in the soil by the pea crop and grazing operations.

Our data on the grazing value of the pea crop are not very considerable, and for the most part refer to early grazing. The reason of this is that we have frequently cut down peas for hand-feeding purposes, whilst at other times we have converted the crop into ensilage, which is generally of excellent quality. Early grazing is due to the fact that hitherto we have looked upon a pea crop as a fallow crop. Our available data are summarised below in Table XIV.

TABLE XIV.—*Showing the Sheep-Carrying Capacity of Peas on the College Farm*—1908-12.

	1908-9.	1909-10.	1910-11.	1911-12.	Means.
	Sheep per Acre.				
April	—	—	—	—	—
May	—	—	—	—	—
June	—	—	—	—	—

Twelve months	1·31	3·61	2·54	1·88	2·34
September-March period (212 days)					4·03

The average grazing capacity of peas proved, therefore, equivalent to 2·34 sheep to the acre for 12 months; or to a little over four sheep to the acre for the seven months that they may be said to have been available —September-March.

LUCERNE.

In referring to the grazing capacity of lucerne, I do not, of course, refer to well-grown crops of this plant under irrigation, or sown in land in which the subterranean water table is within easy reach of the roots of lucerne. I have in view simply lucerne which has been sown in a cereal crop, and which has established itself more or less well in the field. In these circumstances its value for grazing purposes is very great; unfortunately, in our average districts it is no easy matter to get a good stand of lucerne sown in this way; much depends on the character of the season. In our experience one has quite two failures to one success in attempts of this kind. The improvement in the grazing value of the field is, however, very marked; and I am of the opinion, failures notwithstanding, that it is greatly to the advantage of those who keep sheep, to sow 5lbs. or 6lbs. of lucerne to the acre every year with portion of their cereal crops. If the stand of lucerne is good, the field may be left out of cultivation for a period of three years or thereabouts, and when it comes again under wheat it will be found to have gained very much in natural fertility.

Our own results, which are summarised below in Table XV., are perhaps on the whole misleading; they do not do full justice to the grazing capacity of lucerne sown in this way. And this, because only portion of the fields concerned were under lucerne; and it is not possible in our results to dissociate the grazing capacity of that part of the fields that were not under lucerne, from that which was under lucerne. Such as they are, these results are shown below in Table XV.

TABLE XV.—*Showing the Sheep-Carrying Capacity of Lucerne sown in a Hay Crop on the College Farm*, 1910-13.

	1910-11.	1911-12.	1912-13.	Means.
	Sheep per Acre.			
April	1·16	1·00	Nil	0·72
May	1·60	1·77	Nil	1·12
June	2·32	1·83	Nil	1·38
July	0·78	2·98	1·16	1·64
August	1·10	3·18	3·27	2·52
September	2·46	3·44	2·66	2·85
October	1·36	2·74	0·41	1·50
November	1·08	1·26	3·48	1·94
December	2·31	0·46	1·57	1·45
January	0·97	0·48	0·36	0·60
February	0·14	0·04	0·02	0·07
March	0·48	Nil	0·54	0·34
Twelve months	1·32	1·60	1·13	1·35

It will be noted that the average sheep-carrying capacity was only 1·35 sheep to the acre ; this is partly due to the fact that the period covered is only three years, included among which is the 1912-13 season, which was an exceptionally bad grazing year. I repeat that these figures do not do justice to the grazing value of a well-established stand of lucerne.

SOWN GRASSES.

I made the attempt to sow down to English grasses two of our fields ; these comprised perennial rye grass, cocksfoot, Kentucky blue grass, prairie grass, sulla, &c. The grazing capacity of these fields is shown below in Table XVI.

TABLE XVI.—*Showing Sheep-Carrying Capacity of Sown Grasses on the College Farm*, 1908-13.

It may be stated that a sheep-carrying capacity of little over one and a half sheep to the acre for the 12 months does not warrant under our conditions of climate the expense of sowing the land temporarily with expensive grass seed. The grazing value would have been equally good had the land been left out as ordinary pasture.

SORGHUM.

I have, unfortunately, no figures that can adequately picture the value of sorghum to the farmer who owns sheep in the Lower North; and this, in spite of the fact that there is not a year that passes in which we do not take advantage of this crop in some way or other. The position is that in the majority of cases we have looked upon sorghum as a crop more useful to our dairy herd than to sheep; and, with a view to preventing waste, we have generally cut the crop first and grazed-off the second growth. I may, however, be allowed to emphasize the value of sorghum to the owner of sheep. This crop makes summer growth, and, if needed for the purpose, may be fed down or cut in December or January. Its chief advantage, however, lies in the fact that it makes very good second growth, which may be left standing until lambing time, and in which the ewes may drop their lambs at a time of the year, when, apart from exceptional seasons, there is generally a scarcity of good natural feed. It is, of course, true that in most cases the adoption of this practice will lead to the loss of the field for cereals in that season; it can, however, still be sown to peas, and in some cases to barley.

WHAT, ON THESE DATA, IS THE SHEEP-CARRYING CAPACITY OF AN AVERAGE LOWER NORTH FARM?

We have up to the present moment been dealing with figures that represent so many solid facts; by way of concluding remarks, I wish, with your permission, to indulge in a little speculation. Taking the figures that we have been considering as a basis, what should be the average carrying capacity of a Lower North farm?

I propose taking as a standard a farm 900 acres in area, and wholly arable. I shall assume that in each season 300 acres will be put under wheat whilst another 300 acres will be treated as bare fallow. This would leave available for grazing purposes 300 acres, 50 acres of which I shall assume to be under forage crops, viz., 20 acres under rape, 20 acres under peas, and 10 acres under kale. It should be understood, however, that this arrangement is not necessarily one that I recommend; but merely one that I think to be feasible, and which can easily be modified according to local requirements and conditions.

In Table XVII., taking our own figures as a basis, I have calculated out what should be, month by month, the sheep-carrying capacity of a farm laid out on the lines indicated above. It will be noticed that the variations in the area available as ordinary pasture, according as fallowing operations progress, are indicated, month by month, in the first column of the table.

TABLE XVII.—*Showing the Calculated Sheep-Carrying Capacity of a 900-Acre Lower North Farm, Month by Month.*

Average sheep-carrying capacity of a 900-acre farm for 12 months 890

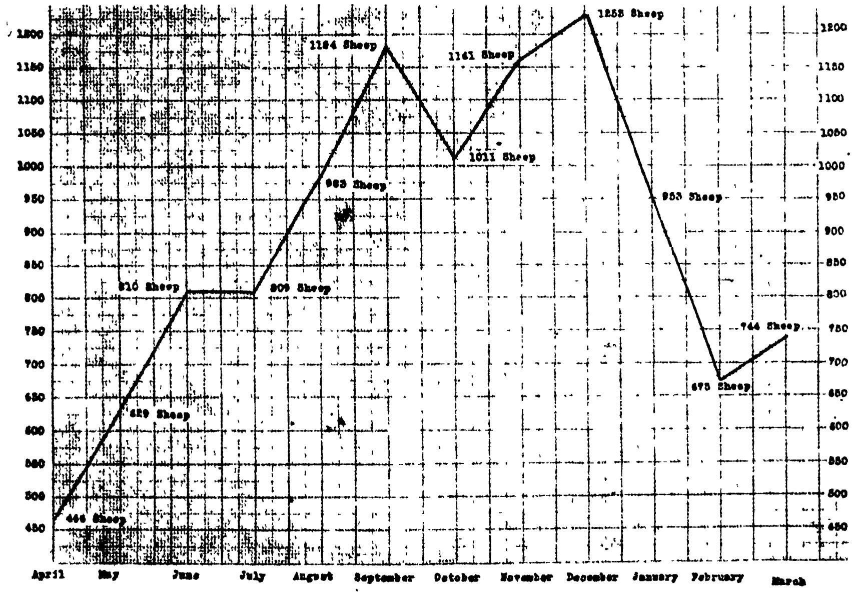

Fig 4 Showing the estimated Average Sheep Carrying Capacity of a 900-acre Lower North Farm, calculated from the 1904-1913 records of the Roseworthy Agricultural College Farm.

Thus, then, on a 900-acre farm, laid out on the lines indicated, we can in average seasons start with 466 sheep in early autumn; the carrying capacity of the farm gradually increases, month by month, until we reach a maximum in December, when the cereal stubbles are supposed to be available;

thereafter there is a gradual decline. The average carrying capacity of this farm is shown to be 890 sheep for the 12 months, *i.e.*, very close on a sheep to the acre for the whole area. It is as well to recollect that these are not merely theoretical figures, but figures based on the results of seven years' experience on the College Farm. It we suppose the farm in question to carry a fat lamb flock—and this, in my opinion, is the least speculative operation which a farmer can take up—if we assume this it can be stated that a 900-acre farm can, in average seasons, carry 450 lambing ewes.

If we examine the last column of the table closely we shall see that the gradually increasing carrying capacity of the available grazing area makes ample provision for the arrival and upkeep of the lambs over the months of May and June; that the carrying capacity of September, October, and November offers ample guarantee for their rapid growth and development; and that the latter months of the season, besides providing for the ewes, make provision for the fattening-off of those lambs that could not be sold as fat off their mothers.

These figures that are summarised in Table XVII. make reference, of course, to average seasons; and whilst in good seasons they will be found to be below the actual carrying capacity of the fields, in bad ones it is equally certain that the figures will be found to be too high. In this connection difficulties will arise mainly in the months of April, May, and June, *i.e.*, the months in which lambs are usually dropped. It is in these months that the number of sheep suggested for a 900-acre farm—450 ewes and their drop—comes nearest to the estimated average carrying capacity of the grazing area. The sheepowner has two alternatives to oppose to these opening difficulties of bad seasons; he may forestall them by having available for the purpose a good crop of sorghum in which his ewes may be turned out to lamb; or else he may concentrate his flock in the home paddocks and feed them on chaff, bran, or any other foodstuff that may be available. In ordinary circumstances these feeding operations are not likely to extend beyond six to eight weeks, and they may be reckoned not to cost more than a penny a head per day.

A Parting Word of Advice.

What I have now to say, by way of parting advice, will be more or less superfluous to those who have already kept sheep under farm conditions; to the unitiated, however, it may have some value. In the first place let me say that it should not be your object from the outset to endeavour to crowd on to your farm the greatest number of sheep possible; but rather that number which is likely to leave you the largest individual margin of profit. Maximum stocking can be undertaken with safety only by those whom long experience has taught how perilous a thing is overstocking. On any farm it should be an axiom that apart from diseased conditions, sheep should never be allowed to get below good store condition ; and when such is not the case, we must suspect overstocking, bad management, or, in very exceptional cases, a very very bad season. Beginners, I take it, must learn to walk before they attempt to run ; they should open up with a few ewes, increasing their number gradually, when they have learnt how to handle sheep to advantage under confined farm conditions, which, it may be added, differ radically from spacious statior conditions. In this connection sheep-proof fences are among the first things that should receive consideration ; and it will soon be found that the ordinary station six-wire fence is not sheep-proof on a farm ; it cannot be said to offer adequate protection to crops that are grown on the other side of it. Further, experience will then show that if a farm is to carry sheep at all in proportion to its area all abnormally large fields must disappear. On a farm on which sheep are kept I look upon 50 acres as quite a maximum in the way of area for all cultivated and grazed fields ; and the need of very many smaller fields will soon be felt it forage crops are to be grown and sheep are to be given those frequent changes of pasture which are so essential whenever they are kept under comparatively confined conditions. Personal experience has taught me that four 25-acre fields, over which the flock is frequently moved, will, in the course of a year, carry nearly twice as many sheep as a single 100-acre paddock, on which they are more or less stationary. Again, from the point of view of the early primeness of the lambs, it is never advisable to lamb much more than 100 ewes together ; nor should the flocks be larger until the lambs are strong and well grown ; this is manifestly an additional argument in favor of a large number of small fields over which the lambing flock may be distributed in the early autumn. A similar line of reasoning applies to the time of the year when the rams are turned out among the ewes ; if a large flock is turned out into an equally large field, the ewes are apt to stray away from the rams, and an irregular lambing and an unsatisfactory percentage are the usual consequences. I am quite aware that the multiplying of fields opens out difficulties in the way of providing them all with an adequate supply of water ; I cannot, however, allow myself to be lured away into a long discussion of this subject ; and I shall content myself with saying that in this, like in most things, where there is a will, there is a way ; but above all things, if you cannot see your way to supplying your flock freely with good clean water throughout the year, give up any thought of attempting to keep sheep on a farm for profit.

CONCLUSION.

I am afraid that I must show some respect for time and some consideration for the patience of the audience ; were it not so, I might find myself involved in the discussion of a hundred and one points, interesting in themselves no doubt, but on the whole foreign to the avowed subject matter of this paper.

It has occurred to me that it may be said that I have chosen a singularly unsuitable season for pointing out to others what I take to be the sheep-carrying capacity of a farm. I freely admit that if we have to go through many seasons such as the present one, the number of sheep which a farmer can keep on his farm to any advantage would be very limited, indeed South Australia has, however, been in occupation for a number of years sufficiently long to enable us to judge of its general agricultural capabilities ; and I am of the opinion that a season such as the present one, or the one that immediately preceded it, does not, in the minds of reasonable men, lower the value of our land one pennyworth. The crops that we have grown we shall grow again in the near future, and probably improve upon them ; the sheep that we have carried we shall continue to carry with equal success ; and the man who is afraid of the future had better make way for another and take up some less arduous, and perhaps less healthful, occupation.

THE DISCUSSION.

The Chairman said he knew very little about sheep, but he had been particularly impressed with some figures recently quoted by the Minister, which showed that the falling off in the number of sheep in the counties of Light and Gawler was, during the last 10 years, nearly 50 per cent. He thought that was to be regretted, because in no phase of agriculture were there greater possibilities of expansion than in the meat trade. The paper was open for discussion.

Mr. A. L. McEwin (Blyth) had listened to the reading of the paper with great interest. He had previously learned a great deal in regard to the keeping of sheep from Professor Perkins, and had profited by his advice. Following on the lines carried out at the Agricultural College he had heavily manured his wheat land. The result was that he had not beaten his neighbors much so far as the wheat crop was concerned, but he had as regards the carrying capacity of the land. He had this year 1,000 ewes and lambs, 22 head of horses, and other stock on 800 acres. He had not hand fed, and the stock were all in good condition. The only crop he sowed specially for sheep was from 100 to 150 acres of oats. He had fed down to September. He would like to know the difference in the expense of raising crops of, say, lucerne, kale, rape, and sorghum. The falling off in the number of stock in the Lower North was easily accounted for. The high price of land had caused farmers to cultivate half their holdings each year. The paper was one of the best ever read at any Congress.

Professor Perkins said it was exceedingly difficult for an experimental institution like Roseworthy College to arrive at a satisfactory estimate of the cost of various crops. They might be able to grow as good a crop as anyone else, but in nine cases out of 10 would not grow it so cheaply. He therefore always hesitated to give costs. He had never grown rape as a crop which received good cultivation. What he had done very often was to put the skim plough over the stubble, break it up 2½in., put a roller over the land, and then sow dry. Kale, on the other hand, had been a more expensive crop, because that had always been sown on land that had been broken up dry to a depth of 6in., and the land had had to be broken down like a cabbage patch. They used about 1lb. of seed to the acre and mixed it with bonedust—about ½cwt. of bonedust per acre. If kale germinated with the April rains they could not get a better fodder for sheep. They could postpone feeding it off to November, and then get feed to February. The sorghum crops had meant very little expense, because it had been sown on fallow. It was mixed with bonedust, like the kale. With lucerne there had been no expense beyond the seed. He had started with 2lbs. of seed to the acre, but had found that unsatisfactory, and had gone up to 5lbs. or 6lbs. This year he had sown as much sorghum as possible. He had sown it in August, but usually did so in September. It could be sown right through the year if there was enough moisture in the soil, but the ground must be warm.

Replying to further questions Professor Perkins said he had come to the conclusion that grazing sheep on land with stinkwort did not do them any harm. At one time he thought there might be something in the contention that stinkwort might perhaps be dangerous when in bloom, but his experience had led him to the conclusion that it was not. He believed in manuring the wheat crop heavily and then, though the full value was not got in the wheat crop, the residue was in the soil, and the forage crops got the benefit afterwards. He used the ½cwt. of bonedust with kale as a medium only for conveying the seed, and used the same quantity with sorghum and rape. He did not, as a rule, manure forage crops.

Mr. H. G. Johnston (Parilla) asked how many wires should be used on a sheep-proof fence.

Professor Perkins, as a rule, thought it wise to put in seven or eight.

Mr. W. Pannell (Geranium) asked for information with reference to spineless cactus.

Professor Perkins had been growing some plants of this during the past two years, and he believed it would be found very useful in dry areas. In Africa the natives used it for feeding all classes of livestock. It took some time to establish, and could not be cut for, say, three years. It would grow from portions of the stems.

Mr. W. Gum (Amyton) asked which would yield the best export lamb in the shortest time, the South Down-Merino cross, or the Lincoln-Merino cross.

Professor Perkins said the matter of the different crosses was a very difficult one to settle. His opinion was that the Lincoln was too large. As a rule the South Down was too small to put direct on the Merino.

Mr. W. Salter (Angaston) asked whether Lincoln cross ewes put to Shropshire rams would yield a good export lamb.

Professor Perkins said that at the College for several years it was found that the Shropshire cross did not develop as well as the South Down.

Mr. H. A. Giles (Mount Pleasant) had kept a crop of kale for as long as five years as a standby. The crop was fed fairly bare, the stock were then taken out whilst it developed, and later put back again.

Professor Perkins had never kept kale for longer than two years. The land was wasting to a certain extent.

Mr. W. E. Hannaford (North Boorborowie) asked whether it was better to grow any other forage crop where lucerne could be grown successfully.

Professor Perkins would keep to lucerne if it could be grown.

Mr. S. H. Schinckel (Naracoorte) stated that chou moellier stood feeding remarkably well. Last year he grew it with wheat and oats.

Mr. Geo. Jeffrey (Advisory Board) expressed his appreciation of the paper. Farmers in some cases were neglecting sheep, and he thought this a great mistake. In order to get over the difficulty of the high prices of land they were endeavoring to get their money back too quickly by cropping at frequent intervals. The bulk of the big stations in the North were being cut up, and to a large extent in the past these had been the source of the supply of fat sheep. He believed that the time would soon come when the bulk of the fat stock in the Adelaide markets would come from the farmers, and the sooner they commenced the systematic keeping of sheep the better for all. The markets of the world were becoming more and more accessible year by year, and there was no branch of the agricultural industry in which there was more scope for development.

In reply to a question from Mr. H. Billinghurst, Professor Perkins said that whilst wire netting was generally too expensive for sheep-proof fencing, it was certainly very effective. The cost of vetches was about 14s. per bushel, and about 20lbs. to the acre was the quantity to sow. He generally sowed the following quantities of the undermentioned grains:—Kale, 1lb. per acre; rape, 4lbs. to 5lbs.; mustard, 2lbs. to 3lbs.; sorghum, 5lbs. to 6lbs.; lucerne, 5lbs. to 6lbs.; and turnips, 2lbs. to 3lbs.

At 10 p.m. Congress adjourned till the following day.

(*To be continued.*)

ALTERATION.

On page 180 of the September issue Mr. A. M. Dawkins, in his address delivered at the Conference of Agricultural Bureau at Cowell, is reported to have said "Formalin had the advantage that it did not retard germination, but it interfered with the working of the seed through the drill." This should read "fungusine."

It is also attributed to him that he used 1oz. of bluestone to a bag of wheat, whereas his practice was to use 1oz. to a bushel.

THE WHEAT MARKET.

Under date London, September 5th, *Beerbohm's Evening Corn Trade List* states—"One of the reasons given for the improvement in the American markets this week is the reported consumption of wheat for feeding purposes owing to the advance in maize prices, but it is impossible at present to say whether the quantity so used will be of sufficient importance to have much effect on wheat values or not. The production of all feeding crops in the United States is very much smaller than last year, when practically all crops gave record yields, so much so that stocks of old maize, oats, &c., at the present time are much in excess of the average. This will modify, to some extent, the effect of the great deficiency in this year's feeding crops, but will not nearly make up for the shortage.

"The shipments from the United States, which have been on an enormous scale so far, are expected to continue liberal, but will no doubt be on more moderate lines than last month, and it remains to be seen whether the exports from Russia will increase sufficiently to make or more than make up for any possible decrease in the American figures. If Russia ships on anything like the lines of 1909, the total exports from all countries will certainly be more than ample for all the requirements of importing countries, at least for the first few months of the present season. The weekly exports from North America to Europe in September, October, and November last year amounted to an average of 616,000qrs., from the Danube 193,000qrs., the Argentine 110,000qrs., India 166,000qrs., and other countries about 85,000qrs. From India and the Argentine exports will probably be somewhat smaller than in 1912, but from the Danube, Australia, and North Africa, together, about the same as in 1912, or possibly a little larger.

(10⅖d. to 10⅘d. per bushel), new season ; to South Africa, 28s. 9d. per ton (9⅕d. per bushel), October-November ; 30s. (9⅗d. per bushel), new crop. Parcels, Port Adelaide to London-Liverpool, 27s. 6d. to 30s. per ton ($8\frac{9}{10}$d. to 9⅗d. per bushel) ; to Continent, 27s. 6d. to 30s. per ton ($8\frac{9}{10}$d. to 9⅗d. per bushel) ; Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel ; to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 31s. 3d. per ton (10d. per bushel), old wheat ; 32 t o 33s. per ton ($10\frac{3}{10}$d. to 10⅗d. per bushel), new crop ; South Africa, 28s. 9d. per ton (9⅕d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on October 1st—

BUTTER FACTORY.

There was a decided increase in the quantity of cream received last month as compared with August, and the quality generally was excellent. Butter was in great demand, and prices were easier at the close than at the beginning of the month. Present quotations are—superfine, 1s. 1d. per lb.; pure creamery, 1s. per lb.

A. W. Sandford & Co., Limited, report on October 1st—

BUTTER.—The production of butter and cream further increased during the month of September, and prices receded slightly, this being more apparent in private separator and dairy lines than in factory and creamery butters. Best factory and creamery, fresh in prints, are selling at 11d. to 1s. 1½d. per lb.; choice separators and dairies, 10d. to 11d.; and store and collectors', 8½d. to 9d.

EGGS.—The strong demand reported a month ago continued, and under its influence prices are very little easier than at the beginning of September. Quotations are—guaranteed new-laid hen, 9¼d. per dozen; duck, 10d.

CHEESE.—Values have kept up fairly well considering the substantial increase from local factories, heavy buying orders for oversea markets preventing stocks from accumulating. Present rates are 5¾d. to 6½d. per lb. for large to loaf.

HONEY.—Supplies of prime clear extracted have not been nearly equal to trade wants, both for local and export. The present price is 3¼d. per lb.

ALMONDS.—It being late in the season there are very few offering. Brandis are selling at 6d. per lb.; mixed soft shells, 5½d.; hard shells, 3d.; kernels, 1s. 5d.

BACON.—High prices continue to rule, owing to the shortage of the live hog throughout the Commonwealth, and values were well maintained during the month. Best factory-cured sides sold at 10d. to 11d. per lb.; hams, 11d. to 1s.; well cut and cured farm middles and rolls, 8d. to 9½d.; country hams, 9½d. to 10½d. per lb.

LIVE POULTRY.—Although the forwardings were extensive, keen competition kept values well up, so that all consignments participated in good prices; the demand bids fair to continue. Good table roosters brought 3s. 6d. to 4s. each; plump hens and nice conditioned cockerels, 2s. 6d. to 3s.; geese, 4s. 6d. to 5s. 3d.; ducks, 2s. 4d. to 3s. 4d.; pigeons, 10d.; turkeys from 6½d. to 10½d. per lb. live weight for medium to prime table birds.

POTATOES AND ONIONS.—It is many years since potatoes were obtainable in September at such low rates as have ruled recently. There are more sellers than buyers, and it appears inevitable that large quantities of off quality lines will be wasted this season. Sellers of Victorians continue to canvass the markets of this State, and in consequence of their operations the stocks held in the Mount Gambier district are not moving so freely as is desirable at this time of year. During the month prices have again eased. Onions.—This market has ruled steady throughout, and there are no indications of any immediate disturbance in values. Quotations.—Potatoes—Gambiers, £3 10s. per ton of 2,240lbs, on trucks Adelaide or Port; 4s. to 5s. per cwt. in the market. Onions—Gambiers. £7 5s. per ton of 2,240lbs. on trucks Adelaide or Port; 8s. to 9s. per cwt. in the market.

RAINFALL TABLE.

(From data supplied by the Commonwealth Meteorological Department).

The following table shows the rainfall for September, 1913, at the undermentioned stations, also the average total rainfall for the first nine months in the year, and the total for the nine months of 1913 and 1912 respectively:—

Station.	For Sept, 1913.	Av'ge. to end Sept.	To end Sept, 1913.	To end Sept,, 1912.	Station.	For Sept., 1913.	Av'ge. to end Sept.	To end Sept., 1913.	To end Sept., 1912.

* No report received during the month of September. † Formal report only received.
‡ Report omitted owing to pressure on space.

Where Branch meetings are mainly occupied with the reception of reports of Congress by delegates these will be classed as "formal."

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

November 12th and December 10th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Coomooroo, September 20.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. E. Berriman (chair), W. Robertson, E. Brice, F. Gregory, L. Avery, R. Brice, R. G. and H. Polden, W. Barber, A. H. Cooke, G. B. Lillicrapp, W. M. Robertson (Hon. Sec.), and two visitors.

Fencing.—Mr. R. Brice read a short paper on this subject. He urged the advisableness of paying attention to boundary fences in particular. Where timber was scarce, one wooden post at each interval of 14yds., with two T iron posts in between, would be found to make a substantial fence. Boundary fences should be wired as follows :—From the ground, first wire 6in., second 12in., third 19in., fourth 27in., fifth 33in., with a barbed wire on top, 3ft. 8in. from the ground. Strainers 3ft. in the ground should be put in at intervals of 8 chains. Wires in division fences could be placed from the ground—first 6in., second 13in., third 21in., fourth 30in., fifth 40in., the latter being barbed. A ⅜in. bit was most satisfactory for boring holes in the posts, as holes of this size did not so readily cause the wire to rust. The bottom two wires should be of No. 6 gauge. Posts should be barked and charred before being put into the ground. Mr. Polden advised two barbed wires on boundary fences, the second being run through the posts, which Mr. E. Brice thought would weaken the posts. Mr. Lillicrapp advised wood and iron posts alternately in boundary fences. Messrs. Robertson and Berriman also took part in the discussion.

Davenport, August 21.

(Average annual rainfall, 9in. to 10in.)

Present.—Messrs. Holdsworth (chair), Bothwell, Messenger, Goldner, Gosden, Sanderson, and Lecky (Hon. Sec.)

Poultry.—Mr. Messenger read the following paper on this subject :—" The maintenance of fowls that are kept in confinement or which have free range, at a minimum cost, requires extensive knowledge, which can only be gained by practical experience. They must be systematically fed under all circumstances. Fowls that have free range find their own living to a great extent, which of course reduces the cost of feeding. A serious mistake is often made by beginners and others who keep poultry in thinking that any kind of inferior grain or food is good enough for fowls. In my opinion, to get the best results one must give good wholesome food. It would be a difficult matter to give the exact proportion and manner in which poultry should be fed. Birds are kept in such a variety of conditions and circumstances that it is not possible to give positive directions to all, A person who observes the methods of feeding will often notice that the birds are overfed; this must be avoided. Hens that are kept for laying only should be kept in a moderate condition, should run for their food, and eat it up greedily. If they do not, then something is wrong with them. and they should be examined. Grain is to a great extent the natural food: but if on free range, where they can obtain plenty of worms, grubs, insects, &c., they should do very well without much hand-feeding. If they are confined in small yards or runs where there is no possibility of finding anything except what is given them, the following rule will be found a good one:—Feed as early in the morning as possible; give them a warm breakfast, consisting of two parts pollard and one of bran mixed with boiling water, not in a sloppy condition, but mixed 'short,' as it is called, which, on being placed in the feeding troughs or thrown down, crumbles. It is a good plan to boil the house scraps, meat, &c., while the fire is going, and in the morning warm them up and mix with bran and pollard, as mentioned. At midday give plenty of green feed, lucerne if possible, and good grain for the evening meal. Some poultry keepers give grain in the morning and mash at night, with green feed at midday. I am not prepared to say which method is best, because both have given good results. Feeding whole grain, wet or dry and no mash, will not produce the best results in laying, as the Maryland Station has conclusively proved. Three pens were tried. The first was fed on whole grain exclusively, the second whole grain and ground feed, and the third entirely on ground feed. The whole grain pen fell far below the others, and the ground fed pen led, although little ahead of the pen fed half and half. Eggs hatched equally as well when the hens were fed with ground food as with grain. They fed wet mash at night (believing it best for fowls to go to roost with their crops full of easily digested food) and grain in the morning thrown into the litter, to keep them busy during the day. Hens that are laying require much more food, also shell-forming material, such as lime in some form or other. Mix a little mortar and place it in the fowl yard so that they can pick it as required; it is astonishing how soon it will go. Also keep plenty of charcoal and grit handy, so that the birds can help themselves. These are all necessary to keep fowls in proper health and condition. Feeding occupies such a prominent part in the management of poultry that serious loss is often occasioned by want of study and observation. There are so many details that have to receive attention that it is wise to consider the best possible method to adopt for obtaining the best results and profit. The highest and best results are obtained by as varied a diet as possible. If eggs are wanted, nothing gives better results than green cut bone, given in fair proportion to other food, 1lb. being sufficient for 16 or 20 hens. But as it is not always convenient to do this unless one has a bonecutter (even then it requires a good deal of time and strength to cut for a lot of fowls), I have used meat meal, supplied by the Produce Department, Port Adelaide, with very good results. I would point out that green bone comprises food, grit, and lime all combined in one. Above all, I would strongly advise that all food given to poultry should be sweet and wholesome, as many ailments can be traced to inferior foods. I am not a believer in hopper-feeding. It is wasteful, and fowls will gorge themselves on whole grain if given the opportunity, and will become fat and lazy. It is far better to feed grain in litter, and to make them scratch it out. This will keep them in a good healthy condition. Careless or indifferent methods of feeding will not give satisfactory results; and if the fancier is not successful in obtaining good results from his stock (provided they are good, of course) he should lay the blame on his own neglect, and not put it down to bad luck." Members were in accord with the views expressed. It was mentioned that although there was abundance of shell grit there was difficulty in obtaining the sharp quartz grit which could be got near Adelaide, where stone crushers were at work. Some members mentioned that they cracked up old broken crockery as a substitute with satisfactory results.

Tarcowie, September 9.

(Average annual rainfall, about 15½in.)

PRESENT.—Messrs. F. Sanders (chair), W. Travers, J. O'Grady, J. Symons, D. Butterick, S. Harding, A. Kotz, M. McCarthy, W. J. Ninnis, W. S. Bennett, J. Dempster, A. Shrowder, G. G. Lines, D. Murphy, P. Reynolds, and M. Murphy (Hon. Sec.).

BEST SHEEP FOR DISTRICT.—Mr. G. G. Lines read a paper, from which the following is taken:—"The most suitable sheep for this district, in my opinion, is the Merino. The country around Tarcowie is very hilly. The hill is the home of the Merino, and the wool grown on hills is of better quality than that grown on plains, because the atmosphere is of a cooler nature, and the soil is not so salty. There is less magnesia, which has a tendency to dry the wool and cause the top to rot, thus reducing its value. The grass grown on hilly country is of a poorer class than that grown on plains, and consequently the lamb industry does not benefit us to the same extent that it does the people living on the level country. Our feed does not grow until September, and we only have it green for a few months. The Merino consists of different types, *i.e.*, the South Australian, the Tasmanian, the Vermont, and the Wangenella. The South Australian, plain bodied, strong woolled, is the sheep for the farmer. As this part is an agricultural district, we require a sheep with a strong constitution capable of eating food that would be wasted with the other stock. Strong wool means strong constitution. The wool of coarse sheep denotes that their skin and bone are of a coarse nature. The Tasmanian strain is a totally different sheep from the South Australian, and a sheep that grows a very fine quality wool, very dense, and carrying a lot of grease. The skin is fine and porous. Every fibre has a tube from the skin which has to be supplied with yolk or wool-fat from the body, and the more yolk the sheep produces the greater is the strain on the constitution. The South Australian sheep are not taxed in this way so much as the Tasmanian. Being of a coarser quality it has not so many crinkles or cups that hold the yolk. The strong wool scours much better than the fine wool, the former will give 50 per cent. wool whereas the fine fleece of the Tasmanian strain will only give about 32 per cent. to 34 per cent. wool. The grease is of no use to the wool buyer, but he prefers a little, because he is then sure that there will be no break. Never go for weighty wool and overlook bulk. The Vermont is a sheep with excessive leather and body wrinkles. It carries wool of wonderful quality, and very dense. In my opinion it is totally unfit for the farmer of South Australia. It requires plenty of green grass. During the last few years the New South Wales breeders have bought heavily in South Australia to cross with their sheep to produce a stronger wool and hardier animal. The Victorian sheep—the Wangenella—is between the South Australian and the Tasmanian. It carries a fleece with plenty of quality and good staple, and has a fair constitution. It has more quality than the South Australian, and more wrinkles on the body. These sheep have been crossed with a lot of the South Australian breeds to give more quality and density, but I am of opinion that these crosses will be a detriment to the South Australian Merino. I am a strong believer in the pure South Australian Merino. By keeping to the pure blood one can rely on the crosses; that is to say, if the sheep are on the strong side one can select a finer ram, and if too fine select a coarser ram and be fairly sure of the results. I recommend strength before quality for the reason that a strong wool sheep will stand more hardships than a quality sheep. The South Australian plain body sheep is a wonderful wool producer, and carries a fleece that always sells well. The commercial value per head will compare favorably with that of any other sheep in the Commonwealth." On September 19th the writer of the paper demonstrated in his wool shed the cleaning of wool, &c., and gave a number of hints of considerable practical value.

Willowie, September 16.

(Average annual rainfall, 11·90in.)

Present.—Messrs. D. McCallum (chair), S. McCallum, I. McCallum, and W. P. Foulis (Hon. Sec.)

Fodder Conservation.—In a paper on this subject Mr. W. P. Foulis drew attention to the necessity for storing food for all classes of stock. The paper read—" Ewes with lambs can be fed during a dry pinch, and this would prevent the lambs receiving a check. Probably, in a season like the present, it would not pay to hand-feed the ewes, but it is not often that we have such long dry spells during the lambing season. It would probably pay handsomely, however, during the short dry periods we sometimes have in April and May. The feeding of milch cows during the times when there is a scarcity of good succulent herbage in the paddocks should also prove profitable. Farmers are often buying butter when they should be selling it. In a district such as this heavy hay yields are not frequent, the district being noted for high grain yields and light straw. The seasons when the hay yields are heavy are the ones when the farmer is busiest, the fallows requiring more working, and laborers are also scarce and wages high. Even so, it will pay in the long run to give attention to this matter. First and foremost I place our present method of making hay; other means are supplementary to it. Every farmer owning 1,000 acres or more should endeavor to maintain a reserve of from 200 to 300 tons of hay. This is not an easy matter. It will be apparent long before hay time that there is going to be a heavy yield; anticipate it, and have all other work well in hand, Make all arrangements for hay-making early. Hire the necessary laborers, have the binders in thorough order. I have come to the conclusion that two binders are necessary. Many farmers cannot afford the first outlay, but those who are in a position to do so will find that it is more satisfactory, enabling them to get more hay down just at the right time, and the hay harvest is not lost if a mishap should befall one of the machines. Begin cutting before the crop is really ready, for in all probability it will be overripe before it is finished; it will also give more time for carting. Put all strength and labor into the work right from the commencement. It is advisable to cut very large quantities when the crops are extremely heavy, as this will relieve the necessity for cutting so much when the grain yield is greater in proportion to the straw. There should be a layer of timber or straw under the stack and one of thatch or loose straw on top. I consider hay chaff, when the hay is obtained from heavy crops, the most economical food for draught horses when only slow work is required of them. Often during our wet seasons good self-sown crops of black oats are grown. These, if cut, carefully stacked, and covered will be found very valuable in dry seasons. In fact, owing to the quantity of well-formed grain they contain, they make useful chaff. I consider it a good practice for farmers to grow from 10 to 20 acres of barley each year and store the grain for everyday use. The straw is short and the grain yield heavy. The grain produced on a given area is more valuable as fodder than the amount of hay that could have been cut from it. By feeding grain with the chaff the hay made in the seasons of plenty is made to last over a longer period, doing away with the necessity for cutting when the crops are light, and there is less work and time attached to gathering the grain. Barley straw can be cut and stacked, it being better for stock than wheaten straw. If grain is used a little of it can be chaffed and mixed with the feed. In Asia, Southern Europe, and Africa horses are fed on nothing but barley and long straw. Grain can be easily conserved, and straw will remain good for years. In times of drought this should prove a valuable fodder. During 1912 the working horses of Roseworthy College were fed on this, with the addition of a small amount of hay chaff, and were never in better fettle. Large quantities of straw should be stacked. This can be done at a time when farmers are not very busy. Salt should be freely sprinkled on it when stacking. I have often seen cattle keeping in condition when feeding almost entirely at a straw stack, and am sure that the mortality among cattle would not have been so great in the past if the conservation of straw had been attended to. The often despised wheaten or so-called 'cocky chaff,' is a useful foodstuff in seasons of drought. When the crops are blighted they are high in nutriment. I have worked my horses lightly on last season's chaff and kept them in good condition. Equal quantities of wheaten and hay chaff with grain make an economical ration. If carefully covered wheaten chaff will keep good for years. An adequate quantity of straw must be properly placed on and then carefully tied down. Farmers have often gone to the trouble of gathering their chaff together and then lost the best of it by faulty covering. It remains for the farmer himself to decide whether or not the chaff is more valuable than the loss of time occasioned by the use of the stripper. Ensilage is no doubt a valuable fodder, but on account of the cost of erecting the silo I do not think it should be stored as a reserve to be carried over several years, but used yearly as a means of lessening the demands made on other foodstuffs. I would provide a fodder reserve in the following order:—First fill the silo with whatever green stuff there is available, then cut and stack hay; in good seasons large quantities. Reap and store barley grain, and after harvest stack straw and gather wheaten chaff together and cover same. This must be done every year when the stuff is available, even if large quantities are already on hand. A few lean years will reduce it considerably, and if done every year the effort to keep up the reserve will not be so great. The heaping or stacking of fodder is not the chief point; the careful using of it is equally important. The feeding and working of horses play a very important part. The practice we often pursue of throwing as much chaff to our horses as they can gorge is not only wasteful but harmful to the animals. The conclusion has been forced upon me that the most economical way of feeding a horse is to limit its chaff and give a small amount of grain. We should also limit the number of working horses to absolute requirements. Care must be taken to get the greatest amount of work out of the teams. A common mistake is to overwork the animals after they have had a rest and are fresh. We go over large areas the first few days, and before we notice it the animals are fagged and slow, when no amount of feeding will get them back to the condition they were in at first. At other times we get over-anxious and endeavor to get over more work by forcing our horses. We do it for a few days, but in the long run it is a case of more haste less speed, and a greater quantity of fodder is required. We must find out what constitutes a fair day's work and stick to it. This will prove to be true economy. By selecting implements and machinery which are light of draught we will lessen the amount of fodder consumed." Mr. D. McCallum thought the conservation of fodder by farmers would to a large extent regulate the very high prices sometimes charged for chaff. Mr. I. McCallum said wheaten chaff would keep for a number of years if properly covered. Molasses sprinkled over straw whilst it was being stacked greatly improved it as a fodder.

Wilmington, September 17.

(Average annual rainfall, 18·26in.)

Present.—Messrs. D. S. George (chair), Hannagan, Duhring, McGhee, Zimmermann, Benier, Gloede, Schuppan, Pickering, Hill, Noll, and B. Jericho (Hon. Sec.)

Grubbing Trees.—In a short paper on this subject Mr. Hill said the work could be made much easier if the trees were rung and left until the leaves fell. The rain which fell would then be concentrated around the butt, with the result that the ground became soft. When the chain and lever gripper was being used particular care should be taken that the anchor chain was stronger than the others, as in the event of this breaking damage would most likely be done to the operator. The height at which the chain was attached to the tree was judged by its strength. If this were put too high quite likely the trunk would break off. If the tree were firmly fixed in the ground it might be advisable to dig a hole in the front and cut the roots, and if this failed, to dig right round the tree, and sever the tap roots. He preferred bark to sap ringing.

Wirrabara, September 20.

(Average annual rainfall, 18·91in.)

Present.—Messrs. E. J. Stevens (chair), C. F. H. Borgas, W. H. Stevens, E. Kavanagh, H. G. Hastings, H. E. Woodlands, F. T. Jettner, G. Hollitt, P. R. Hoskins, E. Hollitt, W. Marner, W. Bowman, S. Thistleton, J. Fitzgerald, A. R. Woodlands (Hon. Sec.).

Shearing.—In a short paper on this subject, Mr. C. F. H. Borgas said the farmer keeping sheep required an arrangement of yards which would allow him to draft and brand his sheep with ease. A well-ventilated shed, grated, and lighted should be provided. It was a good plan to have the grating made in small sections, which could be taken up after shearing, the shed then being used for storing implements, &c. A catching pen and tally pen should be provided, and the stands for shearers should be boarded, so that they might be swept up when the operation was completed. He recommended the farmer with the necessary means at his disposal to put in two or three shearing machines, and undertake shearing on behalf of his neighbors at a reasonable rate. Mr. Jettner preferred blade to machine shearing, and thought that wool-classing should be done before the sheep were shorn. Shearing in hot weather was to be avoided, as there was a danger of the sun affecting the following year's clip. Mr. J. Fitzgerald thought the machines would detrimentally affect the clip when used for a number of years in succession.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Beetaloo Valley, September 15.

(Average annual rainfall, 18in. to 19in.)

Present.—Messrs. J. Burton (chair), A. Jacobi, Ryan, A. and F. Bartrum, Murphy, Reid, Joyce, B. Cox, and Curtin (Hon. Sec.).

Orchard Pests.—The following paper was read by Mr. L. Reid :—" There are several species of orchard pests with which we have to contend. I will deal with each one separately, and class them as I proceed. *Chewing Insect.*—In this class we have only one variety, codlin moth. This pest attacks the apple and the pear, and to destroy it it is necessary to spray with an arsenical compound. The first spraying should take place just after the petals fall, the calyx end of the young fruit is then fully open. When spraying see that some of the spray lodges there, as this is often where the grub enters the fruit. It is necessary to repeat the spraying in from nine to ten days for three times, as there are often two or three hatchings of caterpillars in a season. These pests can also be trapped as follows:—Take a piece of bag about eight inches wide, and so long that the ends will lap about 2in. when placed around the tree; tie it firmly in the middle about 1ft. from the ground, and double the top half down over the lower half. Any grub then crawling up the butt of the tree will go between the folded bag, and, as a rule, stop there. These bandages require attention about every 10 days, the grubs being destroyed. *Sucking Pests.*—These insects breathe through the back, and obtain their nourishment from the tree by boring into the bark. It is of no use spraying these insects with a poisonous composition. What is wanted is a composition that will block up the pores of the back and cause suffocation. In this class we have the following:—Black aphis of the peach, scale, red spider, and woolly aphis. Black aphis of the peach are hard to get rid of; they rapidly increase in numbers and necessitate several sprayings. Tobacco wash is very effective, and may be prepared as follows:—6lbs. tobacco, over which pour 1gall. of hot water and let it steep over night; dissolve 2ozs. to 3ozs. of soap in a quart of water and strain the tobacco wash into this, and add sufficient water to make 50galls. of spray. *Scale.*—The most effective way of destroying this insect is by fumigation with hydrocyanic acid gas under air-tight covers. Spraying with resin wash is very good, and this may be prepared as follows:—Put 10lbs. of washing soda into sufficient water to boil freely, add one and a half pints of fish oil or 5lbs. common soap and 10lbs. powdered resin; boil rapidly for one hour. Add sufficient water to make 50 gallons of spray. Red oil compound is also used for destroying this pest. Red spider is a very minute insect, but can do a lot of damage. Red oil compound is very effective in destroying it. These insects breed very quickly and two or three sprayings are necessary. Woolly aphis keep together in small clumps on the under side of the limbs or between the forks of apples. Red oil very effectively destroys them. The sand fly only attacks the fruit when it is nearly ripe. They suck out the juice and also discolor the fruit, making it totally unfit for marketing purposes. Keep the orchard free from weeds, especially thistles, as this will harbor them. Smoke is very effective in moving them. *Fungus disease.*—In this class we have peach curl leaf and shothole and scab of the apricot. For peach curl leaf Bordeaux mixture is a proven remedy. Spraying should take place just after the flower buds burst. It is of no use spraying if the leaves are out. For shothole and scab of the apricot spray when the blossoms are out and later when the fruit is half-grown. There are several species of birds that the orchardist has to fight against, and they destroy a lot of fruit. The worst of these are crows, starlings, minas, wattle birds, and rosellas. They soon get accustomed to scarecrows and rattlers. Shooting is the best idea. Birds are also one of the main factors in spreading insect orchard pests." Mr. Jacobi favored autumn spraying. For black spot on grapes this year he tried 1gall. of sulphuric acid mixed with 50galls. of water. Mr. Burton used 6lbs. of tobacco waste with 50galls. of water for black aphis on the peach. Mr. F. Bartrum thought citrus fruits the most payable to grow in the district. Mr. Ryan had secured best returns from peaches and Japanese plums. Mr. Jacobi preferred oranges and peaches, whilst Mr. Joyce favored apples and oranges.

Booleroo Centre, September 3.

(Average annual rainfall, 15·83in.)

PRESENT.—Messrs. W. Michael (chair), R. Stunton, B. Nottle, J. H. and J. Repper, J. and B. Kerr, J. Carey, sen., J. M. Carey, J. Carey, jun., W. Whibley, A. Schmitz, G. Ashby, D. Michael, H. E. Kirkland, B. Reichstein, B. Saunders, W. A. Giddings, and O. E. W. Burns (Hon. Sec.)

BULK HANDLING OF WHEAT.—Mr. J. M. Carey read the following paper:—"In the matter of handling, marketing, and shipping produce Australia appears to be behind most grain-producing countries. The elevator system and the bulk handling of wheat are in general use throughout the American continent, the result being less expense, quicker dispatch, and better opportunities for cleaning and grading the grain. Experts who were examined by the South Australian Royal Commission in 1907, which reported on the marketing of wheat, were almost unanimously in favor of the elevator system. The expedition with which wheat can be loaded in ships was testified to by J. M. Sinclair, the Special Commissioner appointed by the Victorian Government, who visited America and witnessed the system in operation. At Duluth, he said, 115,000bush. of wheat were weighed for a ship in 80 minutes, and in three hours three ships, with a capacity each of 80,000bush., were loaded from the elevator. This, he remarks, by our system would have taken weeks. There is no difficulty in dealing with bulk shipments in England. Major Norton, the South Australian Trade Commissioner, said, 'I have seen wheat discharged in bulk at several ports, and people always speak well of the system.' The unfriendly attitude of the wheat merchants has been the principal obstacle. The loss to the farmer in bags alone is a serious item under present methods. The report of the Royal Commission states—'In 1907 bags cost the farmer 7s. 6d. per dozen, and their return value weighed as wheat at 3s. per bushel is only 1s. 10d. per dozen. This represents a loss of £118,000 for a 20,000,000bush. harvest.' The merchants profit to that extent, and this may explain their opposition to any change in the system. Those who say it is no use attempting bulk handling, because the ships so far refuse to carry loose wheat, seem to assume that the export trade in wheat is the only trade. The home consumption of wheat in Australia amounts to 30,000,000bush., and every year the farmers bag that quantity, at a cost for the bags, sewing, and freight, of £300,000, to hand it over to the millers who have erected mill elevators, into which the wheat is emplied in order that they might be saved the expense of buying bags in which to put the flour. No country in the world is better situated than Australia for bulk handling. The harvester reaps, threshes, and cleans the wheat in the one operation, and delivers it loose and ready for the elevator. If the system is undertaken the best method for the farmers to adopt would be to erect several portable granaries of wood, measuring from 8ft. x 10ft. to 15ft. x 20ft., with a capacity of 1,000bush. to 2,000bush. These could be roofed, and when empty could easily be drawn where required. The wagon would need to be provided with movable wheat-tight boxes; into these the wheat could be passed from the granary, through an opening in the roof, either by hand or mechanical means. When the wagon reached the station, after being weighed it could be drawn on to a platform raised sufficiently to cause the wheat to run; a shoot or plug withdrawn, and in a few moments the load transferred to a large bin, whence it is raised by machinery into the elevator building. The farmer would receive his receipt for so many bushels of No. 1 or No. 2 grade of wheat, such a receipt being a negotiable document."

COMPULSORY REGISTRATION OF STALLIONS.—In a short paper on this subject Mr. Reichstein expressed the opinion that the introduction of compulsory registration and examination of stallions would result in an increase in the service fees and higher prices for horseflesh. Farmers just commencing were unable to pay the fees of the high-priced animals, and the proposal would therefore be a hindrance to the expansion of agriculture.

Canowie Belt, August 20.

(Average annual rainfall, 20·04in.)

PRESENT.—Messrs. E. T. Daly (chair), C. W. Dowden, A. F. Dempsey, J. Sparks, A. Kitschke, G. Longbottom, G. Kirk, A. Spavin, J. J. O'Loughlin, R. J. Carter, W. A. Carter, H. A. Wedding, E. W. Noll, A. E. Burton, F. A. Schultz, J. Flower, S. B. Crouch, C. O'Mahoney, A. Noll, H. Schultz, J. Henschke, H. Brooks, J. O'Mahoney, F. Heinrich, H. Cole, and F. D. D. Stapley (Hon. Sec.)

FALLOWING.—A paper on this subject was read, and the following is extracted:—"Land that is intended for fallow should be cultivated after harvest so that the weeds germinate early and a clean crop is the result. The best time to fallow is from the middle of June to the end of August, if it is done later than this it does not give the weeds time to grow before the time for cultivation arrives. Dirty crops in most cases are the results of late fallowing. When fallowed early the land receives the winter rains, so that with thorough cultivation later in spring more moisture is conserved. In this district the best depth to plough is from 3in. to 4in. according to the nature of the soil. Flats and heavy dark land can be ploughed to a greater depth to an advantage. Land that is likely to run together should not be ploughed when too wet; it tends to set very hard, and the cultivator does not tear it up satisfactorily. Ploughing in straw is beneficial in such cases. In September, after light rains so that the top is moist, I advise cross harrowing the ploughing. If a set of heavy harrows is used they not only destroy the weeds but leave the land in a good condition for cultivation later in the spring. After the weather has settled in October the cultivator can be brought into use. This leaves time to go over some again if needed. I prefer the skim plough or a disc where land is suitable for such an implement. They cut and turn the weeds down and leave the land in an even state. The harrows should follow the cultivator, and every fall of rain through the summer months. To have the land in a fine state for seeding is essential. In the absence of rain the seed must be put down into the moist ground under the dry loose top soil and a better germination is assured. Where the fallow carries sufficient grass the sheep can be put on to prevent this going to seed. To plough the ground when dry makes it cloddy and encourages takeall to a certain extent. This can be got out of the land by sowing a crop or two of oats. A crop of oats for hay now and again where land is infested with weeds will help to clean it."

Horses on the Farm.—Mr. R. J. Carter also contributed a paper, in which he said—"It must be admitted that the bulk of the work connected with farming occurs in the paddocks, therefore in selecting or breeding working horses we should give special consideration to the stamp for pace and general usefulness together with capacity for showing condition. Many a horse is of such a build that it never looks well however good its condition. Now a great number of farmers make the mistake of breeding from whatever sire is convenient regardless of shape or pedigree, with the result that a large percentage of the horses on their farms are of a nondescript type: they eat the feed of a good horse, but it generally takes two of them to do a good horse's work. If a man considers the economic working of his farm as well as its productiveness, he will soon find it false economy to keep a bad horse because he bought it cheap, for in lean years, when horse feed is valuable it will soon equalise matters in this respect. The most suitable class of horse for farming in our locality is a cross between the heavy breeds, such as Shire or Clydesdale sires, with the clean legged mares, such as Suffolk Punches. This gives a heavy topped horse on short strong-boned legs, a horse with a stout constitution and plenty of pace, the class of horse that will keep up its condition, because it is the right build for the up and down hill work necessary on our local farms. If a farmer's main object is to raise something for market he should certainly avoid crossing with clean-legged mares, because there is no doubt that the big horse with the heavy legs is the animal to catch the eye and bring the most money. Experience has taught us that this horse is not the best on the farm, but excels in slow heavy road work. It is almost impossible for a farmer in ordinary circumstances to go in for pure bred draughts, because the initial outlay is so great and such a large percentage of good mares prove barren: this generally results in a balance on the wrong side of the ledger. It is a regrettable fact that very few farmers, particularly the young men, take any pride whatever in their teams, and draught horses as a hobby is quite out of the question with most of them. *Roadsters.*—There is generally a great diversity of opinion in the matter of hacks and harness horses. Personally I have had experience with most classes of roadsters, horse and ponies, hackney ponies, Welsh ponies, racing ponies, trotters, thoroughbreds and mongrel breds, and I find most of them good in their place; but some it would be hard to place. In hilly country, as a general utility animal, the pony is of little value. The need of our immediate locality is hacks—the progeny of the rough blood mare mated with the big thoroughbred sire. For harness horses we can mate the same mare with a good sound, clean limbed trotter stallion. The reason for doing this is that the symmetry and characteristics of the sire usually predominate in the progeny, thus giving us the heavier sort for harness and the lighter for the saddle. This same rule applies to draughts, and it would be well to remember that we have a much better chance of improving our stock by selecting good sires than by giving the same attention to the mares, because the sire invariably has a dominating influence. On no account would I use a draught stallion as a means for getting roadsters. Very often success attends the mating of draught mares with blood horses, but to cross them the opposite way is usually a failure. In this district it is best to build stables facing north where possible, as that is the point from which we get least severe weather and more sunshine. The sun helps to keep the stable warm and dry, which is necessary in keeping up the condition of our stock in the winter. If horses come in from work of an evening with a sweating coat and are turned into a bleak, damp stable, no amount of feed, no matter how good it is, will improve their condition. Every farmer should have a couple of stalls at the least penned off to close in any timid animal that may not get enough to eat otherwise, or to shut up the mares in foal and so avoid the chance of their getting bumped. A generous application of the dandy brush on the shoulders will repay handsomely. A little gall cure should be rubbed into any sores on the shoulder. This we find is a very good thing, especially if the horse is not working It is advisable for farmers who crop and fallow most of their ground to have a shelter shed for young horses. To feed these economically it is a good plan to sheave a few loads of good straw and mix with a similar quantity of hay. Put it through the cutter as required and feed it to the young stock in feeders."

Crystal Brook, September 20.

(Average annual rainfall, 15·62in.)

PRESENT.—Messrs. Lovelock (chair), H. and S. Billinghurst, G. Davidson, B. Flavel, H. Growden, R. Heaslip, W. Hutchinson, A. Macdonald, M. P. Pavy, J. Pridham, H. Sutcliffe, H. V. Sargent, R. R. Shaw, J. H. Shearer, J. Teakle, W. J. Venning, M. and B. Weston, A. J. L. Wilson, C. J. Jenner, G. Gum, A. Munday, W. W. Robinson (Hon. Sec.), and one visitor.

SHEEP.—The following is taken from a paper read by Mr. Pavy:—"No animal will shift for itself so well or respond so readily to careful husbandry as the sheep. It is surprising, even to the experienced man, how quickly a sheep will change from a grazier's 'store' to a butcher's 'prime' if given all the suitable food, water, and shelter it requires, not neglecting to increase the value of its fleece—more or less according to the breed—meanwhile. So the question I wish to deal with is: Will it pay to give our sheep more attention in the future than we have in the past? I think it will. America is beginning to realise that Australia can grow wool, and is taking off the import duties on that article. Germany is proposing to lower her import duties on meat. Both countries are extensive buyers, and the Panama Canal is to be opened in the near future, which should mean less freights on some of our exports: factors which point towards an improvement in an already good market in England for such products. Being assured that we have the market, the problem before us is: How can we get the maximum profit out of the land when its carrying capacity varies considerably, even from month to month? The case needs a sound and definite system. The inconsistency of our seasons renders it difficult to formulate one. It is of the utmost importance not to over-stock. Any experienced man knows that this is vital. Four sheep well fed will give better results than six insufficiently fed, and six sheep well fed will give still better results than four equally fed. So in these districts where agriculture has proved successful, and in most seasons heavy crops of wheat, oats, barley, &c., can be grown, it is not wise to let the fear of over-stocking carry one too far the other way, for this also means a decrease in profits. Last year the upper and lower nothern districts carried about 270,000 sheep, Why not increase this number to half a million? Can it be done without lessening the wheat production? The subject is worthy of consideration; worthy of definite experiment to determine how much food a sheep will eat per day? What kinds fatten best? What grow the best wool? What can be most profitably grown without lessening the wheat-producing capacity of land in the various districts? What is the extra cost of hand-feeding over grazing? Will it pay? Professor Lowrie recommends the growing of oats and peas; Professor Perkins recommends growing barley on the stubble, and Mr. Birks, of Wandearah, had met with much success in growing rape in his district. The excellent feeding value of these crops is well known. Success with rape seems to me to be more or less dependent on rain falling at the right time. Oats and barley can be grown during the rainy season and stored and fed when the rain fails. Will it pay better to sell these crops in the form of hay or barley, or as wool and mutton or fat lambs? There is not much data to work upon, but an American authority states that a sheep will consume about 3lbs. of food per day, and 900lbs. of good food will produce 100lbs. of lamb. This, if correct, means about six lambs per ton, or 12 lambs per acre where a 2-ton crop can be grown, and where four lambs can be fattened by grazing 2 tons might be expected if the crop were well put in. At 10s. per head six lambs should result in a return of £3 per ton for hay. Besides seeds of weeds are taken from the land to be returned, after having their germinating qualities destroyed, in the form of manure, adding humus to the soil and promoting the activities of bacteria. At all events one thing is sure—the better feed sheep receive the better they pay, and the better the breeding and selection of breed to suit the conditions and feeding, the greater will be the return. If wool is the chief aim, either the coarse-woolled, big-framed Merino or the medium Merino will be most suitable. The small, very fine-woolled Merino is not suited to farm life. If mutton and fat export lambs are wanted some old English blood is essential. There are about 30 different long and short woolled English sheep. The cross advocated by Professor Lowrie, *i.e.*, Merino and a long wool, say, Lincoln or Liecester for the ewe, mated with a short wool, say Southdown or Shropshire, produces a lamb that for early maturity, quality, and shape is as hard to beat as the Merino is for wool, provided sufficient suitable food is given." Mr. Venning thought the revision of the American wool tariff, the German meat tariff, and the opening of the Panama Canal would provide a great impetus to Australian industries. He had fed sheep on chaff and found it profitable. Mr. B. Flavel thought increasing the stock-carrying capacity of the land, as suggested by the writer of the paper, would be found unprofitable. The only means of storing feed during a good season was by stacking it. Mr. Billinghurst pointed out that the demand for meat throughout the world was rapidly overtaking the supply. The possibility of starvation on this account had been considered by Malthus prior to the opening up of the Russian, Canadian, and Argentine sources of supply. Although his theory had in some quarters been ridiculed, it was quite evident that the problem would eventually have to be faced. Mr. Shaw mentioned the manurial benefits which were derived from sheep on the farm. Mr. Heaslip thought it would not pay to feed these animals on hay costing £4 per ton. Mr. B. Weston had fed a flock this year for three months on short flaggy hay, slightly blighted. Wethers thus fed had realised 30s. per head in the Crystal Brook market (the highest price paid for any sheep during the year). Ewes also did well. He gave one sheaf to every three or four sheep on alternate days. On this the ewes reared an 85 per cent. lambing to excellent condition. It was not advisable during a poor year to keep the animals until the wool broke.

Gladstone, September 6.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. R. E. Lines (chair), W. Brayley, T. Hollitt, T. Mutter, R. A. Humphris, H. Fay, G. M. Black, E. H. Davies, A. B. Blesing, F. Aughey, J. Eley, R. Coe, J. Coe, S. Masters, G. Fisher, J. Page, A. E. Dinning (Hon. Sec.), and four visitors.

ENSILAGE.—The following is taken from a paper written by Mr. G. M. Black on this subject:—" The following can with advantage be used for ensilage:—(*a*) Wheat and oats that have been sown for grain and hay, and in October contain too large a percentage of wild oats and turnips. Portions of these crops, if left, would make very poor hay, and yield very low returns of grain. If cut when green they can be utilised for this purpose. (*b*) If the stock are turned out of the grass paddocks in a good season about the beginning of August, clover, barley grass, &c., will be found growing, and this will make good ensilage. (*c*) Maize, sorghum, peas, and vetches can be grown for the purpose. In our district I believe the cutting out of the portions of the wheat crops dirtiest with turnips would make good filling for a silo, and at the same time it would help to clean the land. No dry fodder must be put into a silo pit. With oats it is wise to cut just as the head comes out. By stacking the fodder a certain amount of waste around the edges is incurred. Pit ensilage is made by putting the fodder in even layers into cemented or earth pits, and taking particular care that it is evenly spread all around the pit. Overhead tank silos are coming more into vogue during the last few years. Hawkesbury Agricultural College possesses a very good one. The filling, which consists of maize, is chaffed before being raised by the elevator. The fodder should be well weighted by means of iron, logs of wood, or bags of sand. An average crop of green stuff yields from 7 tons to 9 tons per acre, and the same crop cut for hay would yield about 2 tons. With the exceptional feeding qualities that ensilage possesses in the production of milk, everything is in favor of the use of the fodder for ensilage. If it is intended to feed it in the paddocks it is better not to cut or chaff it. The temperature of the pit should be kept at about 130° Fah. to get a good sweet ensilage. A lower temperature results in the fodder being too sour. A rough pit can be made at little cost by erecting pug walls and then plastering these. The crop should never be allowed to lie more than four to five hours before being put into the stack or pit. A little rain will not delay operations, as is the case when handling hay. Ensilage can be fed to all classes of stock. Cows and sheep have a special liking for it." In reply to questions, the writer of the paper said the failure to produce sufficient heat by pressure on the fodder was the cause of the ensilage turning out sour. No danger was incurred by putting the crop in wet; in fact, during the latter part of the year it was usually better to do this. About four months after it was stacked the contents of the silo would be matured.

Leighton, August 23.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. A. McDonald (chair), M. Hogan, R. Fairchild, S. Corden, S. Williams, R. Humphreys, T. Goodridge, R. McWaters, A. E. McWaters (Hon. Sec.), and two visitors.

HAY AND STRAW STACKS.—Mr. Hogan, in a short paper, recommended binding and stacking straw as a provision against shortage of feed in dry seasons. Twenty-five tons of clean straw chaffed with 50 tons of good wheaten hay would make substantial feed for horses when they were not being worked too heavily. Cocky chaff and molasses constituted good winter feed for cattle. If possible, lucerne should be grown, the crop being cut and stacked at least twice yearly.

Mundoora, September 22.

(Average annual rainfall, 14·11in.)

Present.—Messrs. W. J. Shearer (chair), J. Clothier, C. H. Button, C. E. Dolling, W. Aitchison, J. A. Owens, J. Stringer, T. Reardon, and G. F. Johnson (Hon. Sec.).

Draught Horses.—Mr. Clothier read a short paper in which he estimated the cost of rearing a draught horse at £17 18s. The service of the stallion cost £2 5s., but as the percentage of foals yielded was about 50, the service fee for each foal could be reckoned as £4 10s. The loss of the use of the mare for two months at foaling and other incidentals brought the total to £7 10s., and two years' feed was estimated as costing £10 8s. He concluded, therefore, that £20 was the lowest price at which a 2-year-old colt or filly could be profitably sold. Mr. Shearer thought the fee of a first-class stallion would be at least £3 3s., and Mr. Button mentioned that the percentage of foals received was sometimes only about 33.

Redhill, September 16.

(Average annual rainfall, 16·79in.)

Present.—Messrs. F. Wheaton (chair), McAvaney, Pengilly, Campbell, Treloar, Coffey, A. and R. Dick, E. Steele, P. H. and F. A. Wheaton, J. Hayes, J. Kelly, W. Hayes (Hon. Sec.), and two visitors.

Dairying.—In a paper on this subject, Mr. Pengilly said that through lack of interest and mismanagement farmers were in some cases allowing their dairy herds to become degenerate and unproductive. Those herds which were a credit to their owners were the result of careful breeding from sires of quality. Where bulls were allowed to run with the cows at all times heifers were brought in too young. He recommended the co-operative purchase of good bulls. Choice could be made from the Shorthorns, Durhams, Ayrshires, Herefords, and Holsteins, but owing to their lack of beef production the Alderney and Jersey were unsuitable for the farmer. The cow that would average 7lbs. or 8lbs. of butter per week for a term of 38 weeks was well worth her place in the dairy herd if she could be disposed of to advantage for beef. The animals should be in full profit during April, May, and June, as there was then generally a good supply of greenfeed available, and good markets were ruling. The co-operative purchase of a milk-testing outfit was also recommended. Mr. Wheaton agreed that it was advisable to systematically test cows. Mr. Coffey thought it advisable for farmers to practice dairying on a larger scale. He favored the Ayrshire. Mr. F. A. Wheaton preferred the Red Poll.

Whyte-Yarcowie, August 23.

(Average annual rainfall, 13·91in.)

Present.—Messrs. G. F. Jenkins (chair), Lock, G. R. and J. R. Mudge, Robinson, A. and F. Mitchell, J. E. and F. Hunt, J. Walsh, G. D. Mudge, E. J. Pearce (Hon. Sec.), and one visitor.

Lambs for District.—In addressing the meeting on this subject, Mr. F. H. Lock said that there was a general idea that the Merinos were most satisfactory in this district, as, should the season prove adverse for fattening lambs, they could be held over for wool, which would in some measure compensate for the failure of the lambs as freezers. Practically, however, there was a difference, as in almost every season some of the lambs were fit for the freezers. These were sent away and the poorer quality stuff was retained on the farm, with the result that the flock deteriorated. If this State was to hold its own in the export market it was necessary that a more shapely carcass should be produced. The Shrop. cross was perhaps the best in this respect, but the wool was so inferior, short, and scraggy as to be a great drawback. The Leicesters, whilst not quite so shapely grew good wool and were good doers. The best lambs for freezing could only be bred from cross-bred ewes, say Merino-Leicester cross, then using a Leicester ram. The main difficulty of procuring a cross-bred ewe then arose. He understood that some of the smaller flockowners on the margin of cultivation were going in for raising stock to supply this demand, and he thought it would pay them well. Attention should also be given to growing fodder for lambs where possible, and there was nothing better than peas if they could be grown. In the discussion which followed Mr. F. Mitchell supported the views of the speaker. He was using Leicester rams, and had obtained a splendid percentage, with practically no lambing troubles. He had lost a number of lambs through the Merino ewes being too woolly, the wool and burrs interfering with the lamb sucking. Mr. G. D. Mudge said the greatest fault he had found with the Leicester was the late and prolonged lambing. The lambs were good and did well. The cross-bred ewes were prolific and good mothers, but they required good fences to keep them in the paddocks. Mr. Hunt preferred the Shrop.-Merino cross for lambs. He had had no experience with Leicesters, but had tried Lincolns and could not recommend them. The Chairman did not agree with Mr. Lock's ideas in regard to the Leicester-Merino cross for lambs. He had tried both and preferred the Shrop. ram and Merino ewe for the conditions in this district. Those who most strongly advocated the Leicester, including Professor Lowrie, did not recommend it for the purpose of breeding a freezer from the first cross with the Merino, but for the purpose of rearing cross-bred ewes, which. when mated with one of the Down breed of rams, would breed the ideal lamb for export. Great difficulty would prevail in farmers breeding cross-bred ewes. It would necessitate the keeping of three flocks on the farm. He thought that the small pastoralist was doing too well breeding pure stock to trouble about breeding cross-breds to supply this demand. He had not attempted to raise his own breeding ewes. If he could purchase a suitable Merino ewe off'shears for 10s. he thought it a better proposition. He did not agree with Professor Lowrie that it was better to pay 16s. for a cross-bred. He agreed with Mr. Lock that selling the best lambs and keeping the culls was suicidal, and should be avoided at all costs.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Blyth, September 20.

(Average annual rainfall, 16·46in.)

Present.—Messrs. A. L. McEwin (chair), J. S. McEwin, J. B. Kuchner, F. Wiltshire, C. W. Zweeh, J. Pratt, A. A. Schultze, W. J. Ninnes, R. Buzacott, C. Lehmann. C. P. Schuster, F. T. Pedler, S. Hamilton, J. Williams, H. Newmann, D. Crawford, J. T. Harmer, A. Dunstone, W. Reinke, jun., J. R. Evans, A. D. Pedler, H. W. Eime, Dr. A. V. Heynemann, W. O. Eime (Hon. Sec.), and five visitors.

Farm Labor.—Mr. A. Hamilton read a paper on this subject. Owing largely to closer settlement, and the quantity of new land being brought under cultivation, he said, there was a growing scarcity of farm labor. The proposal to import lads from England, and train them specially for farm work, was to his mind a good one. Youths naturally adapted themselves more quickly to the conditions of the country, and the three years apprenticeship would not only be in the interests of the employer, but the employés also. He suggested the inauguration of a system of labor exchanges throughout the country, by means of which surplus labor in one district could be drafted to those in which there was a scarcity. Mr. A. L. McEwin thought it better for the farmer to keep a man all the year round at a fair wage, rather than pay a high rate during harvesting. Mr. Wiltshire preferred the employment of the married man, and members generally agreed that the idea of having a labor exchange in each town was a good one.

Gawler River, September 19.

(Average annual rainfall, 17in. to 18in.)

Present.—Messrs. W. J. Dawkins (chair), A. J. Bray, F. Bray, A. M. Dawkins, J. Hillier, G. Higgins, F. W. Roediger, J. Hayman, E. Winckel, B. F. Hillier (Hon. Sec.), and one visitor.

Sheep on the Farm.—In a paper on this subject, Mr. J. Hayman said one of the difficulties of rearing sheep on the farm was that of securing suitable ewes, which had been accentuated since stations in the Lower North had been cut up. Merinos bred in the Far North were not satisfactory; they were often small and very wild; the South bred ewes were better woolled, but seemed lacking in constitution. If English Leicester ewes could not be secured, Merinos should be purchased, but frequently those sold from the stations were culls, coarse, wrinkled, or with yellow, yolky fleeces. If 100 ewes were required, he advised purchasing, say 120, using 20 of the worst for rations. The 100 ewes could be mated with two English Leicester rams, the ewe lambs being kept for breeding. If fat lambs were required it was best to use Southdown rams. If ewe lambs were to be reared a big framed, long-stapled Merino ram could be used. Continuing, the paper read—"The ewe lambs can be kept as before and again put to a Merino ram. The ewe lambs from the second cross to Merino should be put to a Leicester ram; by this means it is possible to rear the ewes required. It is easier to change the rams than the ewes. The sheep described fatten readily, they are very quiet, and the wool sells at a good price. If Shropshire, Southdown, or Dorset rams are used the whole of the lambs should be sold; they are not satisfactory to breed from, the wool is light per sheep and low-priced. There is a difficulty in having the ewes lamb during April and May. If a farmer drives a drill or cultivator during seeding there is no time to look after lambing ewes, and, if neglected, foxes, eagles, and the blowfly soon reduce the profit on a small flock. There is another difficulty; if ewes lamb during the months mentioned stinkwort plays havoc with them, but if they are timed to lamb later, say during June, the stinkwort having died on the approach of cold weather, this trouble is overcome and the sheepowner, having finished with seeding, can look after the ewes. It has always been the practice to get early lambs; the local market is easily glutted, and export buyers do not come soon enough to relieve the position. If the season is good the lambs become too big, or, if the season is not so good, they go off, and lose the bloom so necessary in a good lamb. By having the lambs a little later there is little to fear from cold, as the Leicester seems to be hardy. Also there is a better prospect of good grass by this time and the lambs will grow very fast, and not be stunted as so many early lambs are. These are inclined to get through the fence. Farmers are advised, and rightly so, to use more super. per acre. This brings another difficulty to the sheepowner in the shape of a rank growth of clover, the burs of which stick to the wool and lessen the value considerably. Sheep kept on farms will have to be dipped, on account of the spread of lice. Infested animals will not thrive; they seem to be always rubbing against fences, trees, &c. The wool suffers damage by the rubbing, and a lousy sheep looks ragged, miserable, and unthrifty. Even if the profit does not appear very great, it pays to keep a few sheep. They help to keep the land free of weeds, or at any rate keep weeds from seeding until teams can be spared to work the fallow."

Mallala, September 1.

(Average annual rainfall, 16·88in.)

Present.—Messrs. J. Curnow (chair), F. A. W. Konzag, W. H. Temby, D. Argent, E Penfold, S. J. Temby, J. Nairn, A. E. Temby (Hon. Sec.), and one visitor.

Skim Cultivator v. Plough.—The paper written by Mr. F. Mitchell, of the Whyte Yarcowie Branch, and published on page 1422 of the July issue, was read by Mr. Nairn. In supporting the contentions of the paper writer, Mr. Nairn said his experience went to show that land fallowed with the cultivator gave better results, especially in dry seasons, than that ploughed. The essential, he said, was a fine seed bed with a firm bottom. Mr. S. Temby favored the use of the plough, and Mr. Penfold recommended shallow working and shallow drilling. The disc drill was better than the hoe, as it did not bury the seed so deeply. Mr. Konzag had secured best results from shallow working, and Mr. Curnow recommended the use of either a disc plough or cultivator for fallowing.

Northfield, September 2.

(Average annual rainfall, 19in.)

Present.—Messrs. Williams (chair), Wright, Goldney, Kester, Dall, Rowe, Reynolds, Kelley, and Mitchell (Hon. Sec.).

Feeding Horses.—Mr. E. Kester read a short paper on this subject. Horses, he said, should be fed at regular hours and given as much as they would readily eat. This amount could only be determined by careful observation. It was a mistake to give the animals sufficient to keep them eating all night, and too much chaff did them no good, especially in the case of young horses, as eventually they would not be able to eat long hay. Long feed should be given at night. The subject was discussed at length, each member advocating different methods of feeding.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Bute, September 16.

(Average annual rainfall, 15·42in.)

PRESENT.—Messrs. W. J. Hall (chair), W. Sharman, H. Schroeter, A. Schroeter, B. Lamshed, M. Stevens, W. T. Matthews, E. W. Bettes, and L. E. Simon (Hon. Sec.).

PIG-KEEPING AND BACON-CURING.—The Hon. Secretary read a paper. He advised every farmer to keep two or more pigs, especially if he kept cows. The paper read, continuing—"When pigs are young they only need light food, such as stale milk, slops from the kitchen, or cabbage leaves, &c. Great care should be taken that they are not given too much. The troughs should be well cleaned before any fresh food is put in The amount of food should not be too much at a time, and they should be fed three times a day. Two young pigs, 12 months ago, were purchased at 10s. each. After being fed for about 10 months they were killed, cured, and sold at 10½d. per lb., bringing in £14 for the two. These animals should not be shut in a stye all the year round. There should be a small yard connected with it, wherein the pigs could move about, and they would naturally keep the stye clean, and it would not give rise to such an objectionable smell. This yard could be about one chain long and half a chain wide, fenced with posts, barbed wire, and pig netting. The pigs could roam about in this until such time that they are intended to be fattened for killing. Then they should be closed in their sties and given good solid food, such as pollard or grain. It would pay to keep a good sow to breed the pigs, and it would also pay one farmer in the district to keep a good boar. The best, in my opinion, is a cross between the Berkshire and Poland China. This gives a good streaky bacon. Home-cured hams and bacon, if properly done, compare very favorably with factory cured. After having killed the pig and thoroughly cleaned it both outside and inside, allow it to thoroughly cool down (pigs for curing should never be killed in warm or muggy weather). After it has thoroughly cooled, cut it into such pieces as desired, viz., the hams, the shoulders, and the bacon. The bacon should always be boned. Then give it a good rubbing with dry salt, using about 14lbs. of salt and 6ozs. of saltpetre to about 200lbs. of meat. After having done this place it in a pickling cask or tub, taking the greatest care to protect it from flies. Examine and turn it every week. Leave it in this for at least four weeks, according to the size of the hams. Then take them out, give them a good rubbing with dry salt, using about 14lbs. of salt and 6ozs. of saltpetre, dry them, and strew a little pepper over them, and hang them to smoke. The bacons are better spiced and rolled before being smoked. A smoke house can easily be made with either four or six sheets of 9ft. iron."

Moonta, August 20.

(Average annual rainfall, 15·22in.)

PRESENT.—Messrs. A. B. Fergusson (chair), W. F. Ortloff, W. J. Brinkworth, P. Ford, J. Lawry, and four visitors.

HARVESTING AND MARKETING WHEAT.—Mr. A. B. Fergusson read a paper in which he said—"While the farmer is busy seeking, by improved methods, to get the very best results from the land, the mechanic is also endeavoring to place some machine on the market that will assist him. During the last decade we have made wonderful advancement in this respect since the advent of the complete harvester and the motor winnower, the

Perkin's bag lifter, and the Chapman bag. Wheat harvest work has been greatly facilitated. The first essential in this connection is to see that the machines, whether they be harvesters or strippers, are in a state of thorough repair. Estimate the number of bags required, and have at least two-thirds of them spread out in the sun two weeks before they are used. Bags green out of the bale never fill well and they are hard to sew, and if left standing become slack. Much damage and loss occurs by reaping green wheat. There is much more danger of this since the harvester has been so largely used. We are liable to think that once the wheat is in the buyer's stack it is finished with, as far as we are concerned; but this is a mistake, if that wheat should be stacked green it will probably go musty and weevil will develop. It is our duty to see that our wheat goes into the market in the very best condition. It is well to have a system of standing the bags of wheat in the field. I have noticed a lot of waste, both of wheat and time, through badly placed heaps. Bags fall over, and the person responsible for sewing hardly knows where to start; bags are leaning all ways. The best way is to place three in a row, stand the first three bags so that they will serve as a block on which to lean the others. They can be sown from each end and stood back, and when finished a space is left in the centre to work the loader. When stood in a round heap, which is a common practice, the bags lean all ways, and when sewing is finished bags are standing around in all directions. This is only a detail, but it counts for a good deal when every moment of time is precious. As to the best and most effective machinery, this is a question that every individual farmer must settle for himself, using that machine which he finds suits his conditions and circumstances best. I am a strong advocate of the harvester, and have worked it for 10 years. To go back to the stripper, I would at least want the price of the cleaning as a premium, as I have proved by actual experiment that the harvester gathers more wheat per acre. It must be admitted that our system of marketing wheat is antiquated, slow, and expensive. Of course the elevator system is a big undertaking for any country, but once established is most economical. If it pays in America, why will it not pay in South Australia, which is becoming more and more a wheat-producing country? It has been stated that Canada can place her wheat harvest on the world's market for at least 6d. or 9d. a bushel less than Australia. Thousands of pounds have been paid this year for bags alone. It is a crying shame that farmers should have to pay as high as 7d. and 8d. for a bag, and in a week's time practically give it away to the merchant, who requires it as much as he does; not only that, but the bags that he has given away are actually brought back in 12 months' time and sold to him again at the rate of 5s. a dozen. In an up-to-date wheat yard scales should have no place. Weighbridges, such as are largely used in New South Wales and Victoria, are quick and satisfactory. In New South Wales the Government will put a weighbridge down at any station where 10,000 bags or more are received. These bridges can be put in at a cost of from £60 to £100. The Secretary to the Advisory Board stated that over 100 stations in South Australia received over 10,000 bags in 1910, showing that at least 100 weighbridges were wanted, one especially at Moonta. In the present system of marketing wheat there is no encouragement given to the man who produces and brings to market a clean sample. One can bring in wheat good enough for seed, and another can bring in something a little better than pigs' feed, and they both get the same price. Both are termed f.a.q.—f.a.q. may be a standard for marketing purposes, but it is a farce as far as securing a good sample of wheat is concerned. Professor Lowrie has said the f.a.q. system is not one on which we can congratulate ourselves. and further contends that we are shipping 8,000 to 10,000 tons of rubbish to England every year, and paying 1s. a bushel freight on it, and lowering the name which our wheat holds in the world's market. I consider wheat agents are given too much latitude in receiving wheat that is not f.a.q. They could not accept some lots were it not for the fact that a great deal of the wheat they receive is above standard. Therefore one man has to grow clean wheat to make up for the dirty sample of the other, and gets nothing for it. If producers have the very best interests of the industry at heart they will see that they are bringing to market the cleanest possible sample, in spite of the fact that they get no direct encouragement. Let them take a broader view of it, and seek to keep South Australian wheat at the head of the world's market. Barley in the wheat sample is one thing we must pay attention to. Buyers this season are complaining of it, and rightly so too. The only way of getting rid of it is to weed it out of our seed wheat when it is green. Fixing the standard is another point that is not altogether satisfactory. This season especially the standard was fixed too low, and it has been estimated that we have made the English miller a present of at least 2lbs. to the bushel. If the rubbish were kept out of our wheat the standard could be made much higher. It is fixed on early-maturing wheats from early districts, which are not always as plump as slower and later-maturing wheats in later districts. Sooner or later the elevator system will come ; and the sooner the better, for then we will have a perfect system of grading the wheat. The rubbish that now finds its way into the market will be kept on our own shore instead of being shipped to England and other markets. For the present let us see that as far as possible we keep it at home for pig and poultry feed."

WESTERN DISTRICT.

Butler, September 4.

(Average annual rainfall, 16·61in.)

Present.—Messrs. J. G. S. Morgan (chair), R. W. Phillis, A. Tilly, A. J. Hughes, D. R. Butler, S. M. Bowden, R. Harrowfield, J. C. Humphris, C. F. Jericho, G. Young (Hon. Sec.), and five visitors.

Homestead Meeting.—Members took the opportunity of visiting the holding of Mr. C. F. Jericho. The smithy, stables, enginehouse, stock, and crops were inspected, and the host demonstrated a method of making rope from binder twine. Vines, seven years old, were doing well, but had not yet fruited. A crop, which was cross-drilled with ¾bush. of seed and 1cwt. of super. each way, was looking well. Many ingenious and labor-saving conveniences were noticed in the homestead.

House-Building.—In a paper under this title, Mr. C. F. Jericho advised intending house builders to give careful consideration to comfort before commencing. He preferred a centre passage, leading off into each room, which should possess a fireplace. The kitchen should be large and airy, with the dining-room adjacent, and connected by a door. The roof should be gabled, and the windows protected by a verandah. Outside woodwork required frequent painting.

Coorabie, August 16.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. C. T. Giles (chair), D. Riddle, J. Murray, N. Roberts, W. H. Wheadon, V. Kingsley, C. Hobbs, C. A. Fox, E. Oats, W. Grivell, G. Menzel, A. Riddle, F. Gurney, W. G. Wheadon, F. Underwood, R. Muegge, G. Cabot, H. Coppins, H. Hobbs (Hon. Sec.), and six visitors.

Treatment of Mares and Foals.—The following paper was read by the Chairman :—"Almost the most important item for the farmer to consider in horse breeding is the selection of the mares from which stock is to be raised. Like produces like, and this applies equally to the dam as to the sire. Most farmers are more or less careful in their selection of a sire, but strange to say a great many will put any and every mare they have, irrespective of size or type, to a stallion, and feel disappointed if the resultant stock is weedy. Some farmers make a practice of breeding from a proportion of their mares every other year, under the impression that a foal every year is too much for the mare ; with this I do not agree. I consider the best policy is to select a few of the very best mares, say two or three, and breed from them every year In this way the farmer is breeding the best possible stock from the material he has, and another point is that the mare with a foal is more easily stinted than a dry one. Patronise the best sire available. It is a mistake to spend time and money breeding inferior stock, which requires just as much attention as the best. Experience very soon proves that a mare is not necessarily in foal because she has been served. The disappearance of heat or horseing is the only indication for some time, and even this is not a sure sign, as mares are sometimes known to repeatedly refuse the sire and yet not be in foal. If the mare is in foal she will after a while get sluggish, work steadier than usual, and improve in condition. After about the sixth month visible signs of her condition will be noticeable. Up to this time make no difference in the work given the mare; but after this, which in this district is after the wheat carting is done, she should have lighter work and less of it, and care should now be taken not to drive fast or to give her cause to strain herself. As a rule I never work the mare after seeding, say the end of June, unless she is very fat, which is seldom in this district; but a hard and fast rule cannot be laid down, as a steady worker can be worked with safety much nearer the time of foaling than one that is hot-headed or inclined to 'rip.' Mares should not be given any shaft work within three months of the time of foaling. They carry their foals about 11 months, although the dropping of the first foal is often a little prolonged. My experience is that a filly foal is born almost to the day, and if the mare goes over her time the foal proves to be a colt. At the actual time of foaling the swelling of the udder indicates the coming event, and then a whitish colored discharge, or wax as it is called, appears on the teats. The mares should be put into a separate paddock, but not out of sight of the other loose horses. If not separated from the rest they are often interfered with. If a spare feed paddock is not available, put the mare on the crop in a wheat paddock ; it will do her good and will not hurt the wheat. From the time the wax appears on the teats a watch should be kept on the mare, but she should not be interfered with in any way unless it seems absolutely necessary. If the foaling goes all right the foal will soon be on his legs and trying to suck the mare: and here a little time is well spent watching her, particularly if a first foal, as some young mares are fidgety and will not let the foal suck. In such a case she must be held and the foal given a little assistance, and after once it has sucked there is seldom any trouble in this respect. If the foal is sucking and the mare is quiet, leave them entirely alone, as the mare wants a rest after the exertion of foaling. Before turning them out with the other horses let them first become acquainted while there is still a fence between them. The horses will satisfy their curiosity about the new arrival, and the fence will prevent any damage. This precaution is more necessary in the case of the first foal of the season than with the later ones. If the foal is a healthy one it will thrive and grow quickly and will be a general favorite with the mob. I do not make a practice of working the mare until harvest time, and then for half-days only. The foal should be shut up in a loose box while the mare is away. He will perhaps fret a bit the first day or two, but he soon gets used to it and will be quite contented and quiet as long as the mare is out of sight. It may be necessary to entice the foal into the loose box by leading the mare in for a time or two, but the foal soon gets to know what is expected, and can be driven in quite easily. It is not necessary to have separate stalls or boxes for the mares and foals; it may be better, but I have never found the foal come to any harm running loose and feeding with the other horses. On the other hand, the other horses generally take a fancy to the foal and will let it feed out of the same manger. I have seen animals that are very spiteful to all other horses willingly let a foal push up alongside and share their food. Foals should be weaned when 6 months old, and, provided there is plenty of feed, both foal and mare do better. It is a good plan to teach the foal to tie up while it is about the stable, and once used to being tied it never forgets. Handling the foal will not do any harm so long as it is not played with and teased. Kindness will be rewarded later on and the horse will remember its kind handling as a foal when the time comes to break it in." Mr. D. Riddle would work the mare up to within a few days of foaling, provided she was steady; rough and breeching work, however, was to be avoided. Mr. Menzel would give chain work to every mare that seemed over fat. Mr. Oats agreed. Members were unanimously of the opinion that it was better to give mares expected to foal a free run, rather than keeping them in a small yard.

Farm Wagons.—Mr. G. Menzel contributed a paper on this subject. The English wagon, he said, was the most suitable for general use in this district. It should be about 30cwts. in weight, made of well-seasoned timber, the back wheels 4ft. 9in. in height, and the fore wheels 4ft. 3in., with 13in. boxes, and 3in. axles. The length of the axle from collar to collar should be 5ft. 9½in., width of tyres 5½in. ; the fore wheels having 14 spokes and the hind 16. The axle bed and body bearer should be of 6in. x 6in. stringybark. The body should be about 12ft. 6in. long and 4ft. 10in. wide, which would leave a space of about 6in. clear between the side and the wheels. The height of the side to the inner rail should be about 1ft. 6in., to the outer rail 1ft. 9in. If the height of the front were 4in. greater than the back it would bear the weight of the load more to the centre. Draw bars were more satisfactory than having the pull on to the shafts; the bars should be fixed to the caps on the outside of the wheels. Several members thought a wagon of the dimensions mentioned too large for a farm. Mr. W. H. Wheadon preferred light hind wheels. Mr. D. Riddle favored the table top. A straight bar from the box axle to the bottom of the king bolt would be an improvement on most wagons. The Chairman thought it important to have the ends of the shafts shod.

Miltalie, August 16.

(Average annual rainfall, 14·55in.)

PRESENT.—Messrs. T. A. Wilson (chair), J. P. and I. W. Story, H. Brine, J. S. Jacobs, W. G. Smith, C. and A. Degner, P. G. Wilson, E. Story (Hon. Sec.), and four visitors.

THE AGRICULTURAL BUREAU.—In a paper under this heading, the Chairman pointed out that in the scattered districts where the carrying on of a literary society was impracticable, the Agricultural Bureau was of considerable value from an educational standpoint. He suggested that each Branch should formulate a set of rules for the regulation of meetings. Homestead meetings and experimental work were matters that should have their place in connection with the Bureau, and a library would be found of considerable benefit. Members generally agreed that homestead meetings were of value.

Miltalie, September 13.

(Average annual rainfall, 14·55in.)

PRESENT.—Messrs. P. G. Wilson (chair), C. and A. Degner, J. P. Story, H. Brine, H. R. Jacobs, C. E. and S. R. Searle, M. H. Wilson, W. G. Smith, E. Story (Hon. Sec.), and nine visitors.

FARM MANAGEMENT.—In a paper on this subject, Mr. C. Degner said that the more land was worked in this district the better chance there was of favorable returns. Horses should be fed and watered regularly, and provided with good stable accommodation, each having a stall to himself. It was a good plan to breed a few foals each year to supply any vacancies in the team. There was less likelihood of trouble with sore shoulders if the animals were groomed regularly. The harness of each should be in its particular stall, and should be oiled once or twice a year, and kept in good repair. Attention should be given to the fences, and where barbed wire was used, care should be taken that none of it was left lying about loose. Cocky chaff mixed with crushed oats and wheat made a good horse feed, and hay and straw should be kept as a fall back in case the season failed. A few cows, pigs, and poultry could well be included in the farm stock. In discussing the subject, Mr. J. P. Story agreed that a great deal of working was necessary for the land in this district. Sheep, he thought, were a great help to the farmer. Mr. S. R. Searle advised the keeping of cocky chaff, and thought oats a better feed for horses than wheat. Mr. W. E. Hier did not approve of single stalls for horses. The Chairman, Messrs R. Smith, W. G. Smith, and F. Turner (a visitor) also took part in the discussion.

Roberts and Verran, September 16.

PRESENT.—Messrs. R. Johnson (chair), F. Masters, A. T. Cowley, W. Kunst, C. Kunst, C. Reiman, F. Imhoff, A. J. Buttfield, W. Sharman (Hon. Sec.), and one visitor.

FARMING NEW MALLEE LAND.—In a paper on this subject Mr. W. Kunst said that for clearing heavy timber logging would be found the best method, but with light scrub the use of the roller with knives was most satisfactory. The work should be done as early as possible to give the shoots a chance to grow before the scrub was burnt. He would only cut the springbacks in an area of about five chains wide around the land being cleared. This would give the fire a good start, and it would be found that sticks left standing after the fire had gone through the balance would be more easy to knock down than the springbacks would be to cut. Before burning he would throw in a break about half a chain wide. About the middle of March was early enough for burning. This would leave time for treating any pieces that the fire missed. He recommended working the land to a depth of 1½in. to 2in. with a skim plough or a tine cultivator as soon as possible after the fire had gone through. For later wheats about 45lbs. of seed per acre should be sown, but for the early varieties it was advisable to put in 1bush. to the acre. Usually 56lbs. of super. would be sufficient, but if the seeding were late more would be required. As a rule crops in this district were not thick enough to enable the harvester to do good work, and where the stripper was used there was the additional advantage of the cocky chaff being saved. On the completion of the harvest the fire rake should be put into the stubble. In discussing the subject Mr. Masters said he would use the plough in preference to the cultivator, as the former turned in ashes and other substances that helped to strengthen the crop. He thought the harvester the best method of gathering grain. Mr. Cowley preferred rolling the crop before harvesting, as the shoots would then have started by burning time, and they would be more severely checked by the fire, Mr. Imhoff favored rolling after harvesting, and would use 56lbs. of super. if sowing early in the year, but 50lbs. when seeding late. In the first year he would put in a bushel of seed to the acre, thus securing a better stubble for burning. The Hon. Secretary favored using 45lbs. of wheat and 56lbs. of manure to the acre. Mr. Johnson said that in taking up a new farm the landholder was well advised to sow an area with about a bushel of oats to the acre and about 45lbs. of wheat. He preferred the skim plough, and thought it best to cut as many springbacks as possible. Members generally agreed with the recommendations of the writer of the paper.

Utera Plains, September 13.

(Average annual rainfall, 12·06in.)

Present.—Messrs. Guidera (chair), J. and M. Abrook, W. Gale, H. and G. Hornhardt, G. and H. Barber, W. Lee, jun., H. Warner, and A. Ramsey (Hon. Sec.).

Papers from "Journal."—Three papers from the *Journal of Agriculture* were read by Messrs. W. Lee, Guidera, and G. Hornhardt. With regard to co-operation, members were of the opinion that this would be satisfactory where men of sufficient business knowledge were secured to control the operations, and it was realised that loyal support was a most important factor. Various members recommended different methods of handling young horses.

Yadnarie, September 13.

(Average annual rainfall, 14·09in.)

Present.—Messrs. W. L. Brown (chair), J. A. and E. C. Kruger, G. A. Dreckow, A. Sprigg, A. A. Jericho, R. H. Parbs, F. H. Stubing, B. B. Crosby, J. J. Deer, F. G. Fitzgerald, R. B. Deer (Hon. Sec.), and nine visitors.

Spring v. Bridle Ploughs.—Mr. F. H. Stubing read a paper on this subject. The spring draught release ploughs, he said, were best for use in stumpy and stony country. If a bridle plough were being worked up hill with the full draught and a stump were encountered the shoulders of the horses would be jarred, and in all probability sores would be the result. When this implement was being taken down hill, very frequently it would run on owing to its own weight, the ploughs being worked with the points of the shares only scratching the surface. None of these difficulties would be met in the spring draught plough. Members were strongly in favor of the use of bridles on ploughs in level country, as more stumps were dragged out of the land and less trouble was encountered with the implements. In hilly country the spring draught plough took the ground better and rode more easily over the stumps.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Claypan Bore, September 5.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. J. Gray (chair), S. Gray, H. and H. Colwill, J. Northey, C. Dunstone, M. Robinson. C. H. Russell, J. Dudley, F. S. Tall (Hon. Sec.), and five visitors.

Cost of Wheat Production.—Mr. J. Northey supplied the following estimate of the cost of growing wheat in mallee country. The estimate was based on the case of a person working 500 acres. One bushel of wheat per acre, 3s.; 75lbs. of super. per acre, 3s.; wages and keep of one man for 12 months, and an extra hand at harvest time, 5s. per acre; 5 per cent. depreciation of stock, plant, &c., consisting of 12 horses, harness, two harvesters, wagon, binder, plough, cultivator, drill, and harrows, 1s. 6d.; hay, cornsacks, pickle, twine, &c., 4s. 6d.; a total of 17s. per acre. Mr. Gray said the first and second crops

were the cheapest to grow. With a good burn the land could be worked with a tine cultivator as efficiently as with a plough. The cost of rolling and clearing should not be charged against the first crop, but treated as an improvement. Mr. L. McCormick (a visitor) mentioned that it was necessary to take into consideration interest on the land value, and members agreed that with an allowance of about 2s. per acre for this, the estimate of the writer of the paper was correct.

Coomandook, September 20.

(Average annual rainfall, 18·01in.)

PRESENT.—Messrs. Ninnes (chair), Legallez, Lubcke, Driscoll, A., R. A., and L. A. Williams, Luxmore, Hillman, Hughes, Blucher, Cordes, M. Wilkin, C. Wilkin (Hon. Sec.).

FARMING IN MALLEE LAND.—Mr. M. Wilkin read the following paper:—"The most suitable time for starting a farm in mallee land is about the beginning of July. This gives time, with the help of a man, to prepare for a crop the following year. Two weighty young horses of active stamp and a tipdray are necessary for carting. The first thing is to make provision for water. This is most important, as no farmer can prosper who has to cart it. A well or a bore is best, but where good water is not obtainable in this manner a cement tank with a large catchment should be put down; £50 spent on this is not too much. A hut to live in and a stable come next. With one's own labor those can be erected very cheaply. In a district where stone is available nothing else should be used for the walls. Structures of this substance are far more weather-proof and add much to the value of the property. The timber and iron for roofing can be purchased for about £40. The hut should be roomy, so that afterwards it can be utilised for a barn or storeroom. The stable should have accommodation for six horses. with chaffroom attached, and be built so that it can be enlarged at any time if necessary. About the beginning of October four more horses of the same stamp as the others will be needed for scrub-rolling; a roller can be built for £10, and 400 acres should be rolled by the end of November. Wheat always grows better after early rolling. When this is done the place could be left for three months. Being harvest time, a man with a good team should be able to earn £60. After burning the rolled scrub about the end of February one could plough up about 20 acres of good soil and sow with barley or rye. This would come up with the first rains and save a considerable amount of horse feed. A cultivator should be put over 300 acres as early as possible to prevent ashes drifting. About the middle of April drilling could be started and finished by the end of May. The remaining 80 acres of cleared land could be fallowed and cross-ploughed during the next two months. By doing this a considerable amount of roots would be torn out and a good hay crop ensured for the following season. As soon as the fallowing is finished the horses should be paddocked to keep the chaff bill down. It will be necessary to fence the crop to prevent stray stock trespassing. A wooden post every chain and one tee iron between each with two barb wires can be erected for £40. All posts should have six holes bored in them. so that extra wires can be added at any time with very little trouble. At least 50 acres should be cut for hay. In a fair season this should return about 25 tons; 8bush. of wheat could be expected. All stubble should be burned, and the land ploughed as soon as possible and sown again. If cropped three times in succession and stubble burned each year, practically all the roots would be killed. Expenses for the first 18 months would be—Horses, £150; water, £50; hut and stable, £40; dray, £20; roller, £10; seed and super., £60; seed drill, £50; plough and cultivator, £60; fencing, £40; horse feed, £50; harness, £15; tools and breakages, £20; living expenses, £40; wages, £40; binder, £38; stripper, £65; winnower, £28; total, £776; against sale of wheat, £262 10s.; money earned, £60; total, £322 10s. To start farming on this scale a man would require a capital of £585. Of course a good deal could be saved by buying second-hand implements, but to do this successfully one must have a thorough knowledge of machinery. I would warn anyone against the time-payment system, because one always pays at least 12 per cent. for the accommodation, and if dry seasons are experienced it is often difficult to meet the payments. By putting substantial improvements instead of the temporary ones usually erected to save time, one can always get assistance from the Government if needed, should there be a failure in the crops." **Members thought a 20,000gall. cement tank large enough for the purpose mentioned by the writer of the paper. After a clean scrub burn if a cultivator were taken round the plot, and strips worked with this implement, drifting would be checked to a large extent. A skim plough could take the place of the plough and cultivator during the first year.**

Coonalpyn, September 19.

(Average annual rainfall, 17·49in.)

PRESENT.—Messrs. H. Bone (chair), J. Hill, G. H. Wall, R. F. Venning, J. J. Cronin, A. H. Fidge, D. T. Cronin, F. J. Tregenza, J. F. Pitman, J. Angel, G. E. Venning (Hon. Sec.), and 11 visitors.

SPRING WORK IN THE GARDEN.—In a paper under this heading, Mr. J. F. Pitman said orchard land should be harrowed and then cultivated with a spring tooth implement in the spring, to kill weeds and assist in the conservation of moisture. Apricots, plums, and especially peaches should be thinned, if necessary, to ensure a good sample of fruit. Apples and other pip fruits should be sprayed against codlin moth, and grafting and budding should receive attention. It was advisable to work the land after every rain of consequence that fell prior to Christmas. In reply to questions, Mr. Pitman said he preferred budding to grafting. This work should be done in the spring, and he strongly advised pruning young trees. Almonds, which had not borne fruit, should be budded, as they seldom fruited unless this were done. No harm would result if vegetables were grown for three or four years between young stone fruits.

Forster, August 23.

(Average annual rainfall, 10in. to 11in.)

PRESENT.—Messrs. J. G. Whitfield (chair). W. J. and T. Searle, W. J. and F. Johns, R. Whitfield, R. Copp, P. Purdie, J. Stone, C. Hayman, E. Towill, and C. Payne (Hon. Sec.).

SEEDING OPERATIONS.—In a paper on this subject, Mr. R. Whitfield recommended the use of the four to eight furrow plough, according to the available strength. The land should be broken to a depth of about 4in., harrowed in the same direction, the seed being drilled in the opposite way. The width of the drill should not exceed 17 discs. After this the harrows should again go over the land. The stripper was better for use in sandy and stumpy land, but under suitable conditions the harvester was a decided improvement. Members generally agreed.

HORSES.—Members generally were of the opinion that the practice of purchasing old horses for use on farms was to be deprecated.

Monteith, September 26.

(Average annual rainfall, 14in. to 15in.)

PRESENT.—Messrs. T. S. Bradford (chair), R. Magor, J. Ferries, W. G. Gunn, H. Gardner, O. E. Male, C. J. Morris, T. R. Smith, A. A. Wells, J. Rowan, A. Clark, W. H. Carter, W. S. T. McCulloch, W. J. McCulloch, J. F. Connell, L. Bell, A. P. Mount-Stevens, D. McDonald, C. A. Bentley (Hon. Sec.), and a few visitors.

CO-OPERATIVE CHEESE FACTORY.—The Hon. Secretary delivered an address, in which he urged the erection of a co-operative cheese factory in the Monteith district. He gave interesting details with regard to the general working of such a scheme, and mentioned that a city produce firm had expressed their willingness to assist in the undertaking.

Pinnaroo, September 20.

(Average annual rainfall, 16·74in.)

PRESENT.—Messrs. Roy Edwards (chair), A. U. Burman, F. G. Bonnin, L. M. Ferguson, Geo. Fuller, F. Laycock, B. H. Nash, A. I. Reed, T. B. Shiels, H. Venning, W. Wilson, and P. H. Jones.

ENSILAGE.—Mr. L. M. Ferguson supplied a paper on this head. The writer based his remarks on practical experience, both in Victoria and South Australia. He agreed that it was somewhat early for this district to resort to such a method for the preserving of fodder; but he was sanguine that the time would come when it would be necessary to combine wheat-growing with the raising of stock. Then it would be advantageous to have reserve feed to tide through a dry autumn or winter. He advocated the cutting of grasses, preferably wheat, oats, or sorghum just prior to its being in a fit state for hay. He would use a pit, timbered at the sides but with the natural earth flooring. It was advisable to keep the grasses well damped as the pit was being filled, and to allow the whole a couple of days for settling down before weighting. A thick layer of straw under the weight prevented the admission of air, and consequently improved the quality of the ensilage. Members generally agreed with the writer in respect to it being rather premature to make ensilage in this district. The Chairman had used chaffed maize, but it was too rich, consequent upon its having been cut on the ripe side. He mixed it with dry hay chaff. He found no disadvantage in the cement pit.

Parilla, September 19.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. H. G. Johnson (chair), C. Foule, P. J. Brown, M. Rush, P. Harrip, L. Foule, P. N. Lewis, G. Gregory, J. Lee, M. McAskill, G. Mendorf, S. Evans, A. J. Stevens, J. H. Daniel, Phil Harrip, J. H. Dewhirst (Hon. Sec.), and one visitor.

FALLOWING.—Mr. E. J. Keeley read a paper on this subject. As the land in this district was free from weeds, and several successive crops destroyed large numbers of shoots, he said, fallowing was not considered necessary during the first few years. However, this was now becoming essential. The sooner after seeding the land was ploughed for this purpose the larger was the amount of water it would take in. The weeds also germinated earlier, and could then be destroyed when the land was worked over in the spring. The ploughing should be to a depth of 4in. on the firm soils, but 3in. was sufficient on the sandy land. This rendered it more easy to cultivate the land to different depths. It was inadvisable to fallow stubble, on account of the liability of the crop to be attacked by takeall; the best practice was to fallow every third year. If the soil became hard it might be advisable to go over it lightly before ploughing. The addition of fair dressings of super. to the fallow would encourage a good growth of feed for stock. Mr. Daniel advised working the fallow after every rain. Mr. Gregory thought it necessary to work it in October, and keep the surface loose. Mr. Stevens recommended lightly skimming the land after harvest and ploughing it when seeding. He would fallow to a depth of 3in. the first year.

Waikerie, September 15.

(Average annual rainfall, 8·89in.)

PRESENT.—Messrs. E. J. Burton (chair), F. B. Williams, W. J. Green, S. Modistach, R. Stanley, J. C. Walters, F. G. Rogers, and Jno. J. Odgers (Hon. Sec.).

THE SULTANA.—Mr. W. J. Green read a paper, as follows:—"I have found the Sultana vine with irrigation tends to throw out an abundance of wood, mostly rank, and little fruit. The present style of pruning in my opinion is too severe; there are not enough rods left to carry fruit, four canes to a vigorous vine not being sufficient. The Sultana should have at least six good canes, using a three-wire trellis, the permanent arm to be taken to the second wire, and the rods up and down. The trellis I am using for my young vines is made with this end in view, and consists of three strong posts 7ft. 6in. long, two as strainers and one as a centre post 4ft. 6in. above the ground, with six iron standards between. The first wire is 2ft. from the ground, there being 14in. between the second and third wires. The rods should be taken to the first wire the third year, and during the fourth year taken to the second wire, when the permanent arms should be formed. The third wire is not wanted until the fifth year, when the vine is furnished with plenty of canes. When pruning select short-noded wood, not too thick, and take two good canes for each wire; the length of canes varying according to the strength of the vine. Leave spurs of two eyes in suitable positions for next year's fruit wood. A good setting results from twisting the canes around the wire, taking care that each node cracks when it is being twisted. This causes a slight fracture to the cane and steadies the flow of sap, acting much the same as a cincture on the currant. I have found that the cincture on the sultana causes weak wood, and generally weakens the vine. In spring all buds below the arm should be rubbed off. Reserve all likely shoots on the spurs for next year's canes and rub off those not required. Topping for a second crop is a bad practice, especially on the Sultana, as it tends to weaken the vine. The leaves are the lungs, and by removing these the vine is injured. Grapes exposed to the sun are tough-skinned and inferior in quality as compared with fruit shaded by the foliage, and no light-colored Sultanas can be obtained where there is a lack of this." Mr. Green said the length of rod for a vigorous vine 6 to 8 years old was 4ft. or 5ft. The chief factor with the Sultana was disbudding. Barren buds should be rubbed off. Spurs should be left in a suitable position for wood. Cincturing the canes might be useful. A good average crop was about a ton per acre. Mr. Stanley generally agreed with the writer, but thought he advised too great a length for canes. This year's rods should come from wood that bore fruit last year.

Wilkawatt, September 20.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. D. F. Bowman (chair), W. J. and D. Bowman, jun., C. and T. Sorrell, J. and A. V. Ivett, E. W. and H. H. Brooker, T. Sorrell, A. J. McAvaney, F. and B. Spackman, W. R. and M. Neville, F. W. and E. Altus, B. Tylor, W. J. Tylor (Hon. Sec.), and seven visitors.

PIG-KEEPING.—Mr. W. R. Neville read the following paper on this subject:—"This should be looked upon by the farmer as one of his most profitable side lines, and with a reasonable amount of care should pay handsomely. The sheds or sties should be warm, and yet have a maximum of ventilation, and face the north. The floor should be of concrete, or bricked, to allow of thorough cleaning. A good supply of bedding is necessary. The yards (there should be more than one) should be periodically spelled, root crops being grown in those that are not being occupied. In breeding, the boar is the first consideration, and should be purebred and pedigreed, if possible. Avoid inbreeding, as the ill effects of this quickly show in pigs. The Berkshire or Tamworth is recommended, as these are both good doers and vigorous. The sows should not be put to the boar before they are 10 months old, and when in pig should be allowed plenty of exercise to avoid getting too fat. When farrowing, cleanliness should be one of the first points, and care should be taken not to excite the animal, or she may become savage and develop a liking for eating her young. In addition to milk, &c., a liberal supply of greenfeed in the way of lucerne, also mangels and turnips, should be given. The latter can be grown to advantage in the yards not being used by pigs, and will considerably lessen the cost of feeding. The animals can be fed in this way until within a fortnight of being killed, when they can be hardened off with grain, and at the age of 6 to 8 months are ready for the market." Mr. W. J. Bowman favored the Berkshire-Tamworth cross, as they gave the best bacon. Milk and greenfeed, with peas or wheat to finish off, was considered the best ration for fattening.

MARKETING WHEAT.—Mr. F. W. Gasmier contributed a paper, in which he stated that the farmers, under the present system of disposing of their produce, were entirely in the hands of the merchants. This position was due to the union existing amongst merchants throughout the world. London was the centre of the world's market. This was their centre of action, and the producer had no say in settling the prices for their produce. To rectify the position the farmers should unite throughout the world and co-operate through their unions. They should build mills in suitable centres and grind all wheat to first-class flour, instead of shipping the wheat and allowing the labor to be taken from these shores. The flour could be shipped to depôts and there retailed to the consumer without the intervention of the middleman or merchant. It would be necessary to get the bakers to join the union by offering a bonus on their purchases. If these proposals were carried out farmers would in a few years arrange their own prices for their marketable goods.

Wynarka August 29.

PRESENT.—Messrs. J. R. Beck (chair), C. B. Wright, G. G. Pitt, A. W. Laurie, J. Boyce, W. Boyce, W. Sweetman, A. Hood, A. McDonald, G. Masson, C. Schultz, J. Schultz, J. Murphy, M. F. Gates, J. Carlysle, C. S. Hall (Hon. Sec.), and two visitors.

FALLOW.—Mr. W. Boyce read a paper from which the following is taken:—"The object of working the fallows early in the spring is to keep a mulch on the surface and so conserve the moisture in the soil. Mulches act by breaking the connection between the surface soil and that beneath. The more thoroughly this connection is broken the more effective will the mulch be. The plough, by cutting off a layer of surface soil and returning it loosely, makes a more effective mulch than any other implement. Until this has been destroyed by rain and other natural causes, nothing will be gained by working the land and breaking down the rough surface; to do this would be rather a disadvantage; for it will have a tendency to re-unite the soil, thus strengthening its capillarity and increasing the flow of water upwards to the surface to be lost by evaporation. Even if the ploughed surface has become somewhat settled, and therefore less effective, little will be gained by working it in the early spring if it has been a wet season. After dry weather conditions set in the amount of working the fallowed land requires will depend upon the climate

and the condition of the soil. Professor King, of Wisconsin, found as the result of experiment, that in seven weeks the loss of moisture from unmulched ground was equivalent to 170 points of rain more than from mulched land. If the moisture is to be saved the soil must be stirred as soon as the effectiveness of the mulch is destroyed by rain." The majority of members thought the harrows the best implement for working down the fallow.

SOUTH AND HILLS DISTRICT.

Blackwood, September 15.

(Average annual rainfall, 27in. to 29in.)

Present.—Messrs. W. L. Summers (chair), P. H. Williams, Gamble, A. A. Magarey, Eglinton, Sibley, Penno, H. and L. Sullivan, Hilfers, James, Davis, Savage (Hon Sec.), and two visitors.

Principles of Cultivation.—Mr. H. E. Sibley read the following paper:—"The main question we have to consider under this heading is, why do we cultivate? Firstly, to deepen the soil volume within which the main feeding roots of the plants are placed. When we sow a crop we crowd into a limited space a greater number of plants than would grow naturally, thus limiting the surface area within which they are able to grow. Greater depth will give rise to stronger individual plant development. Plants are not always unable to penetrate deeply in untilled land, as roots find their way downwards in fissured or cracked soils, however small these fissures may be; but tillage renders this penetration into the subsoil general and not accidental. Secondly, the growing tips of roots must be able to breathe, and they are unable to do this unless a well-conducted tilth is provided. Thirdly, tillage operations regulate the water supply of the soil, by helping to store up moisture at wet times for the benefit of crops sown at later periods. If the water is in excess, tillage operations spread it evenly and reduce the danger of waterlogging. Loss through evaporation is also reduced. When the rain falls on the hard untilled ground very little penetrates below the surface. The bulk lies on the surface, runs away into creeks, or is evaporated. Quite the reverse happens with loose, broken earth, which acts like a sponge and is capable of absorbing a large quantity of the rainfall. It also transmits it to the subsoil beneath. In a dry country like ours, this may be considered one of the principal objects of tillage operations. The following is taken from a bulletin of the Illinois Agricultural Experiment Station:—'Tillage or cultivation also hastens the liberation of plant food by permitting the air to enter the soil and burn out the organic matter; but it should never be forgotten that tillage is wholly destructive; that it adds nothing whatever to the soil, but always leaves the soil poorer. Tillage should be practised so far as is necessary to prepare a suitable seed bed for root development, and also for the purpose of killing weeds, but more than this is unnecessary and unprofitable in seasons of normal rainfall.' It will be seen from the above that in the humid climate of Illinois, conservation of soil moisture is of so little importance that cultivation is actually condemned beyond strict limits. With our dry climate, on the other hand, conservation of moisture is very essential. This shows how very careful we must be in attempting to apply the cultural experience of other countries to our own conditions, when there is so much difference in climate. When soils are tilled, they are opened out so that air, water, and all the other weathering agents have free access to the individual particles of the soil, and the result is that the minerals on which plants feed are rendered more readily available. Phosphates, potash, and calcium salts become more soluble. Organic matter is broken down and split up into nitrates. Indeed, all processes that contribute towards the fertility of soils are hastened. Finally, tillage has also the effect of destroying undesirable weeds, and thus helping the growth of cultivated plants. *Capillarity.*—Whenever a lamp is lighted, there is at once started a current of oil rising through the many spaces between the threads of the loosely-woven wick, and this flow continues so long as the oil is removed from the upper end by burning. So, too, when a wet soil is exposed to a drying wind, the removal of water from its surface results in setting up a flow from deep in the ground, upward, toward and to the drying surface, to make good these losses. Then, again, when the root of a plant threads its way among the soil grains and withdraws from their surfaces a portion of the water with which they are charged, there are at once set up, to make good this loss, currents of water travelling from various directions in the soil towards the absorbing root. If a clean glass tube ·055in. in diameter is placed upright in a vessel of pure water at a cold temperature, the water will be seen to rise on the inside to a height of 1in. above the surface of the water in the vessel, and the smaller the diameter of the tube is the greater will be the height to which the water will rise in it. In a tube 1in. in diameter the water will rise ·054in., and in a tube ·001in. in diameter the water will rise 4·56in. The molecules in the glass are stronger than those in the water, consequently the water is drawn up the tube. In the soil the small fissures act as the capillary tubes through which the moisture is drawn upward. The different forms of tillage are classed as follows :—(1) Ploughing, (2) harrowing, (3) cultivating, (4) rolling, (5) horse-hoeing. Firstly, we will deal with the plough. If the work of a plough were perfect it would, in principle, reproduce exactly the work done by a spade, *i.e.*, completely turn over a slice of earth. In practice, however, the plough is far from equalling the spade in its work. The soil may, perhaps, be as well loosened, but it never is so effective in completely burying weeds as if the land were dug. The plough is the main implement in use on farms for breaking up land, which is usually ploughed roughly, and the cultivators, harrows, and rollers usually prove sufficient to provide the necessary degree of tilth. There are four types of ploughing—(1) surface, or skim-ploughing ; (2) average depth ploughing ; (3) deep ploughing ; (4) subsoil, or trench ploughing. Of course these are only relative terms. What is deep in one district is shallow in another, and *vice versa.* Generally, however, shallow ploughing varies from 2½in. to 4in. This is used to break up burry land, or where the soil is thin and crusty, and overlies raw subsoil. The bulk of South Australia's fallowing is done on this system, and therefore 4in. must be considered average ploughing. Generally, average ploughing means 6in. to 8in., and is done about every two or three years on land which is shallow ploughed. Deep ploughing is reckoned about 8in. to 10in. This depth is broken in preparing land for special crops, *e.g.*, root crops, or crops that are likely to be in the soil some years, such as lucerne. Subsoiling means 12in. to 18in., and is practically only used in preparing orchards and vineyards. The time to plough requires careful consideration, according to the local conditions prevailing. As a rule the first ploughing should commence as soon as possible after the first good autumn rains, and the more rain the land receives after it is broken up, the better is the store of moisture for the plants or trees, and the quicker and stronger will they grow. Light sandy soils can be ploughed almost at any time, so it is just a question of doing it at the most convenient time to fit in with other work. The character of the implements used in the cultivation of the land has a very important bearing, both on the progress of the work and its ultimate results. That type of land which is stony and rough does not make ploughing with the fixed plough desirable, on account of likely injury to the ploughman and also to the extra cost of breakage of shares. The stump-jump plough, therefore, is in every way preferable. South Australia is the home of this plough, which was invented by a South Australian. Directly the share touches any fixed obstacle, the section carrying it is lifted or jumped clear of the stone or root, after which it returns to its normal position. These ploughs do, as a rule, very good work and are especially adapted for cultivating where any rough, stony, or stumpy land occurs. The conformation of the field is important. Flat or gently undulating ground may be ploughed as desired. Steep fields or orchards require special attention. If the ploughing is straight up and down the field the soil is washed straight down the hill, and also the draught is very heavy. It would appear wiser, then, to have a furrow running along the hill, but even with this method there is a danger of washing when the furrow overflows. The best way is to plough obliquely, and so conduct the waterflow on a gentle slope. The objects of harrowing are as follows :—To drag out weeds incompletely buried by the scarifier or plough. To bury seed which has been broadcasted. To kill weeds just germinated. To bury manure which has been broadcasted. To reduce soil to a fine tilth and consolidate it. The quicker harrowing is done the better it is done as a rule. It is best to harrow in one direction and then cross harrow. If the soil lies in the furrow, the first harrowing should be in the direction of the plough. Cultivation corresponds to light second or third ploughing, but the soil is not turned over. The object is to scrape up the surface which has become consolidated by rain, and also to destroy weeds. It levels down the soil and provides a healthy seed bed, and may even help to cover the seed. There are numerous forms of cultivators, but they are all used for the same purpose. Land is rolled for the following reasons :—To consolidate the land, especially light sandy land, when ploughing has been late and rain scanty. To crush clods when the ground is rough, particularly on heavy land ploughed too dry. On the growing crops to make them stool or tiller. Ordinary cropping land is lightly rolled to prepare the land for harvesting machinery. To bury fine seeds, such as grasses and clovers; there are several forms of rollers, namely, wooden, which is the oldest in use and is very useful for light rolling; iron cylinder, which is usually used for rolling crops; Crosskill clod crusher, which consists of a series of narrow plates fitting loosely to a central axis, and carrying on their surface a series of teeth—these rollers are very heavy, but are exceedingly useful for rough and uneven ground in dry countries; Cambridge roller, which consists of a series of discs or rings with sharp edges—being placed side by side these edges present a corrugated surface and are well suited for rolling crops. The horse-hoe is a small cultivator usually drawn by one horse, and is used mainly for cultivating between the rows of root crops, such as potatoes, mangels, &c., where the rows are about 2ft. or 3ft. apart. The most widely used form of horse-hoe is the Planet Junior. This implement has a lever to regulate the setting of the tines according to the width of the rows. It is exceedingly handy in vineyards, and is generally used during the summer to kill weeds. There is also one other advantage in that it can work quite close to the vines."

Mr. A. A. Magarey also treated with this subject in the following paper:—" Everyone must find by experience what is best suited to his particular soil, and should have a definite reason for every operation in connection with cultivation. It is no uncommon thing to hear a man say he is working on a certain system, for no other reason than that he knows someone else who does it that way; on the other hand, there is the man who will not use a certain method because he gets along all right without it, and never troubles to find out whether he would not do better by altering. The most important reason for cultivation in a dry climate like ours is the conservation of moisture in the soil, to enable the crop to grow through the summer. It allows of the free entrance of air. which is as important to the growth of a plant as moisture. The absorption of moisture from the air by the soil is most important in a dry climate. There is always moisture present in the air in the form of vapour, even in the hottest weather. This fact accounts for the presence of dew. This vapour in the warm air comes into contact, during the night, with the cooled surface of the earth, and condensation results. If the air is allowed a free passage through the surface soil a fair amount of the moisture lost during the day by evaporation will be returned during the night by condensation. A dry, peaty soil will absorb as much as one-twelfth its own weight of moisture in a night in this way, a clay soil not quite so much, and sandy soil least of all. It will be seen, therefore, that the amount of moisture a soil will absorb is dependent upon the amount of vegetable matter and clay it contains' It should be well worked, and humus added either in form of stable or green manure. The deeper it is worked the greater quantity of water will it be able to take in without becoming waterlogged, and the greater amount will it be able to retain, and the better able will it be to chemically decompose new material into plant food. The disadvantages of continual shallow ploughing are that a hard pan is formed. The point of the plough scrapes over this and plasters down the under surface of the soil. In heavy soils this hard pan restricts the free passage of water and air either downwards or upwards. In light sandy soils this does not occur to any extent, and it will be noticed that these soils are generally ploughed deeper than the heavier ones, when the reverse should be the case. As a remedy to this hardening of the under surface of the soil. it is advisable to continually alter the depth to which the ground is ploughed, and every few years it should be ploughed as deep as possible without turning the subsoil to the top. It would also be beneficial to subsoil every 10 years or so where possible, as this helps to drain the land more thoroughly. Also the surface soil gradually mixes with the broken subsoil, which has been acted upon by air, water, and frost, and thereby increases the depth of the soil. The summer working should be very shallow, stirring to the depth of a few inches with a scarifier being quite sufficient. This forms a loose mulch on the surface, and therefore prevents loss of moisture by evaporation, as capillary attraction is not strong in very loose soil. Scarifying kills grass and weeds and thus prevents loss of moisture in this way. It will be found beneficial to run the scarifier over the surface every two or three weeks, whether rain has fallen or not."

Cherry Gardens, September 17.

(Average annual rainfall, 35·03in.)

Present.—Messrs. H. Jacobs (chair), J. Lewis, G. Hicks, C. Ricks, T. Jacobs, sen., J. Tozer, A. Broadbent, H. Lewis, T. Jacobs, jun., H. Jacobs, C. Jacobs, A. R. Stone (Hon. Sec.).

Fencing.—In introducing a discussion on this subject, Mr. J. Tozer recommended pegging out a straight line for the fence so far as possible. The wires would then be much easier to keep tight. Under ordinary conditions stringybark would be found suitable for posts, but where white ants were troublesome, blue, pink, and especially red gum were to be preferred. The posts should be split to a width of 4in. or 5in. at the top and placed between 9ft. and 10ft. apart, and not less than 20in. in the ground. Strainers should be not less than 9in. across the top, of good solid wood, and from 2ft. 9in. to 3ft. in the ground. Struts for the strainers should be placed squarely on the adjoining posts at the butt ends a little below the surface of the ground. To put the strut close to the top of the strainer tended to raise the post out of the ground instead of firming it. The top wire should be about 2in. or 3in. from the top of the post, thus being 3ft. 9in. from the ground. Four No. 8 wires should be placed at equal distances between the top wire and the surface of the ground. Mr. Ricks thought it advisable to have two barbed wires in a fence.

Forest Range, September 11.

(Average annual rainfall, 35in. to 36in.)

PRESENT.—Messrs. W. McLaren (chair), J. Vickers, J., H., A., F., and E. Green, H. Schultze, F. and E. Rowley, H. Sass, H. Waters, J. Coulter, R. Collins, and O. S. Pollard (Hon. Sec.).

FUSICLADIUM.—Mr. E. Rowley mentioned that he had tried both limewater and Bordeaux mixture for spraying apples affected with this disease, but had noticed no difference in the results. Mr. J. Green favored Burgundy mixture, and Mr. Vickers would use soda in preference to lime, as it had not such an injurious effect on the spray pump.

Gumeracha, August 19.

(Average annual rainfall, 33·30in.)

PRESENT.—Messrs. A. Moore (chair), D. Hanna, J. Monfries, J. B. Randell, B. Cornish, H. V. Cornish, H. W. Norsworthy, W. B. Randell (Hon. Sec.), and one visitor.

HISTORY OF THE GUMERACHA BRANCH.—A paper on this subject, of considerable local interest, was read by Mr. D. Hanna. He mentioned that the inaugural meeting was held on the 9th July, 1888, thus this was the fourth Branch of the organisation formed. The apple export trade in its very early stages had received practical encouragement from the Branch. Many agricultural practices now in general use were originally introduced into the district through the agency of the Bureau. Since the first gathering, 184 meetings have been held, 84 papers on agricultural matters being read by members. The paper was much appreciated, and eulogistic reference was made to the excellent work done by the writer during his 25 years' membership, and also to that of Mr. W. Green.

HEREDITY.—At a previous meeting, Mr. J. Porter read a paper under this heading, in which he said—" Very few men to-day wishing to breed a horse for any particular purpose would choose a sire possessing none of the characteristics desired, but would secure one with the qualities required in as marked a degree as possible. It is not so long ago when any horse, if a low price were asked for his service, was very much in demand. The men who made use of the animal thought that by getting cheap foals they were doing best. It is satisfactory to know that this state of things is fast passing away. By studying the subject a little more closely, however, I think much better results can be obtained. It is not so much to the breeding of stock as to plant life that I wish to direct attention. If we recognise the fact that like produces like, or that plants as well as animals have the power of transmitting characteristics, we shall be more careful in the selection of the seed we use. Numbers of farmers now use the grader with good results, but it would not be wasted time or trouble if they were to carefully select seed from the most healthy and prolific plants only. One who looks closely at a growing crop will notice that some plants are much stronger and healthier than others growing beside them. It may be said that the more vigorous plants have had a more abundant supply of plant food, but I am inclined to think that if the seed of the more vigorous plants were gathered and planted side by side with seed taken from the weaker ones we would find that the seed of the strong plant would produce the better crop. Up-to-date nurserymen advertise trees propagated from proved fruiting trees only, and it is the general practice of the gardener to keep the best plants for seed. The increased cost of production makes it necessary to get the best possible return for our labor and outlay, and if the returns can be increased by careful selection, it will be well worth our time and trouble to give it a trial." Mr. J. B. Randell mentioned that scions taken from fruiting and prolific trees came into bearing much earlier, and bore much better than others; the same principle held with regard to saving seed from early and prolific cereals and vegetables. Seymour attributed the running out of potatoes to the practice of planting small, rubbishy tubers, instead of selecting seed from large sets. Mr. H. V. Cornish agreed. Mr. D. Hanna believed it paid to breed from the best. Members generally supported the idea of the writer of the paper.

Inman Valley, August 13.

(Average annual rainfall, 26in. to 27in.)

PRESENT.—Messrs. H. J. Meyer (chair), J. W. Crompton, H. G. Allert, H. J. Jagger, H. J. Dennis, H. Gray, H. I., H. T., and R. J. Martin, D. A. Nosworthy, H. Mitchell, J. A. Lee, V. G. Tugwell, M. J. Meyer, J. G. Barratt, R. A. Mayfield, E. A. Scarfe, J. Millard, G. and A. McCoy, L. V. Hurrell, H. M. Parsons (Hon. Sec.), and one visitor.

WATTLE CULTIVATION.—In a paper on this subject, Mr. R. J. Martin said wattles could be grown to a fair size on almost any scrub land, if not planted too thickly. The land should be roughly ploughed twice with a stump jump implement before the wattles were planted. This killed most of the natural scrub, and minimised the risk of bush fires. Three or four pounds of seed boiled for a few moments should be sown to the acre, the harrows being then put over the ground. If the nature of the land was too rough for ploughing, good results might be secured by using a grubber, or the dry seed might be scattered through the scrub, which should then be burnt. The falling price of wattle bark, however, did not warrant very careful cultivation. In discussing the subject, most members agreed that it did not pay to cultivate the wattle on land that would grow feed for sheep, as the price received for bark was not sufficient to pay the cost of stripping, carting, &c., and return a profit.

SHEEP DOG TRIAL.—On the motion of Mr. H. J. Dennis, seconded by Mr. D. A. Nosworthy, it was decided to hold a trial of sheep dogs under the auspices of the Branch, and the following committee was appointed to make arrangements, *i.e.*, Messrs. H. J. Jagger, H. J. Dennis, J. W. Crompton, H. T. Martin, H. J. Meyer, and the Hon. Secretary.

Kanmantoo, September 13.

(Average annual rainfall, 17·90in.)

PRESENT.—Messrs. R. Downing (chair), A. Stewart, R. Critchley, H. Downing, E. Shepherd, W. C. Mills, S. C. Downing, A. Mills, H. R. Shepherd (Hon. Sec.), and two visitors.

DESTRUCTION OF RABBITS.—In a paper under this heading, Mr. E. Shepherd stated that if systematic and simultaneous efforts were made to cope with this pest, a great deal more good would be done than by the haphazard methods at present in vogue. He recommended poisoning as soon as the grass became dry, either by using a poison cart or by putting down a plough furrow and in this placing a number of baits of different poisons. When the ground became wet, trapping and digging out should be resorted to. Stones should be rammed into rock holes. Wire netting was of greatest value where the country was not too rough, 3ft. 6in., 1¼in. mesh netting being used. The paddocks enclosed in this way should not be larger than 500 or 600 acres.

Longwood, August 16.

(Average annual rainfall, 37in. to 38in.)

PRESENT.—Messrs. W. H. Hughes, A. F. Furniss, H. Winter, J. C. Blakley, E. Colbey, J. Brown, E. A. Glyde, J. Roebuck, E. J. Oinn, W. G. Doley, T. Hill, J. R. Coles (Hon. Sec.), and four visitors.

EARLY CULTIVATION IN ORCHARDS.—In the orchard of Mr. A. F. Furniss, at whose homestead the meeting was held, it was noticed that Clairgeau pears were blossoming, and that ploughing amongst the trees was almost completed. Members who favored the practice of ploughing early, *i.e.*, before August, maintained that with the possibility of dry seasons, it was very beneficial, and if cultivation were carried on throughout the season the weeds would be kept well under control. On the other hand, it was contended that the land was apt to become puddled, and washing was encouraged. Frequently the weeds were started, but owing to the continued wet, it was difficult to get on to the ground, and they became too strong to be dealt with by the scarifier. October ploughing enabled the weeds to be turned under, and the soil was left in good condition for aeration.

Onion Growing.—The following paper was read by Mr. J. Roebuck :—" In this district, where the holdings are small and the late frosts often destroy or damage crops such as potatoes, beans, tomatoes, &c., onions are being more extensively grown each year, as they are considered a safer crop. When selecting onions from which to grow seed, first decide whether the onions are for late keeping or for marketing straight off the land. The hard keeping sorts do not crop nearly so heavily, and they are not so juicy and mild in flavor. Further, the plants are more difficult to raise in this cold and wet district than the softer sorts, which will not keep long. It is a good practice to grow both an early and a late sort. The seeds must be grown a good distance apart, as they readily hybridise. Select sound, fair sized bulbs of good color, firm right up to the neck, which should be small. Plant them in rows 2ft. apart, the bulbs being 1ft. apart in the rows. Bury the bulb, leaving the neck out of the ground. Not more than three or four rows should be planted in one patch, or they will be found difficult to hoe and keep clean when the seed stalks are grown. Plant keeping sorts in July. Soft sorts will have to be planted earlier, as they will have started to grow. The ground should be well manured and deeply dug. Cut off the seed heads when the black seeds begin to show. Spread them on sheets of iron to dry, and then thrash them out ready for sowing. New seed will germinate quicker and grow stronger than one year old seed ; after two years it is not much good. The most difficult part of onion cultivation here is raising the plants, as they have to grow through the cold winter months. Select a warm sunny slope if possible for the seed beds. A well drained sandy loam is best. Dig in a good dressing of stable manure early in March. Then put another dressing of short stable manure on and hoe it in. This keeps the surface loose and gives the young plants a good chance to break through the ground. Give it a good watering, if possible, to start the weeds before the second week in April, when the first onion seed should be sown. If they are sown earlier they may run to seed when planted out. Sow at two or three different times, about a week apart, or all the plants may be ready at one time and some may become too old in the seed bed before they can be planted out, with the result that they may go to seed after they are planted. Sow the seed in drills about 8in. apart and 1in. deep. Leave every seventh drill unsown and the patch will be in beds of six rows each, with a 16in. footpath between each bed. This leaves room to get amongst the plants to hoe and weed them. Make a wooden drill that marks out six or more drills at one time. Raking the bed lightly just when the first plants break through the ground saves a lot of weeding afterwards and does not hurt the crop. If the plants are at all backward water them with rather strong liquid fowl manure or sulphate of ammonia. When they are nearly the thickness of a penholder they are fit for planting out. In drawing them from the seed beds shake the soil from the roots and put them in straight bundles. They can then be more quickly planted. If the plants are too long, cut the tops back with a sharp spade while the bundles are on the ground. Never cut the roots. It pays to manure the land well. Put a dressing of stable manure on in the autumn. Plough this in and leave it until planting time. Then put on 5cwts. of good bonedust per acre, and plough or dig the land deeply. I usually plough two furrows deep, *i.e.*, about 10in., but I have always had the best crops from dug land. Then put on another 5cwts. of bonedust per acre and harrow, if the land has been ploughed. Rake it fine and mark out in the same way as was done with the seed beds. No line is needed, as the first line of the drill is drawn along the last line made. Tread out every seventh mark, leaving the patch in beds of six rows each, 8in. apart, with a 16in. space between. Plant three rows of onions from each side of the bed, setting the plants about 4in. apart. A good planter will put in about 10,000 seedlings in eight hours. The plants should be straight in the rows, so that a wheel hoe can be worked close up to them. This is much easier and quicker than hand hoeing. It is important that growing onions should be kept free from weeds. In places where water is available using sprinklers is better than running the water on, as it can be more evenly distributed. If the onions receive a check in a dry spell they are liable to be attacked by thrip, which may reduce the crop very considerably. It is not necessary to break down the tops when the onions are nearly ripe. When the tops have fallen of their own accord the onions should be piled and placed in rows to dry. Cover them with the tops, weeds, or anything handy, or the hot sun may scorch them. In a few days the tops and roots should be cut off, and if early sorts, they should be bagged up ready for market. I have found it a good plan to put keeping onions into banana crates and stack them on the ground for a few days to dry them before taking them into the store. They may be stored 3ft. or 4ft. deep on a wooden floor, which should be at least 1ft. from the ground, on shelves in the storeroom, or left in the crates under a shed. They should not be left in bags. It is important to have them thoroughly dry when storing. This crop may be successfully grown on the same land for years, but I think it is better to alternate with some other crop. They can be grown on a variety of soils, but a deep, dark, sandy loam will yield good crops of good quality. They involve a good deal of work, but a crop should return from 10 to 20 tons per acre. I have taken 4cwts. to the rod from a small patch, which would work out at 32 tons per acre." The writer of the paper demonstrated the methods he adopted in planting. He advised manuring and preparing the land early, and watering where possible, to start the weeds: they were then easier to destroy. The seed bed should be left loose after sowing, in order that the plants could make their way through. The seed should be put in to a depth of 1in. Plants should be put in just sufficiently deep to make them stand upright. Frosts did not directly damage the plants, but might cause the soil to become hard around the roots. The tops of onions should not be cut, but allowed to die down.

STRAWBERRIES.—Members had tried replanting strawberries, but did not think it profitable. The bushes ran out much more quickly than those in virgin land, and a great deal of attention was necessary to keep down the weeds. The general practice was to plant them among the young trees of the orchard, where the continuous working was beneficial to the trees. With good attention, and replacing the few plants which failed each year, the strawberries might be grown until the size of the trees demanded the selection of a new site for the plot.

Longwood, September 13.

(Average annual rainfall, 37in. to 38in.)

PRESENT.—Messrs. W. H. Hughes, E. Colbey, E. J. Oinn J. Roebuck, A. F. Furniss, E. A. Glyde, J. Brown, W. Nicholls, and J. R. Coles (Hon. Sec.).

VINEGAR-MAKING.—In a short paper Mr. E. H. Glyde said he had secured best results by cutting up two and a half cases of apples and adding to this 1gall. of water. The process took about 12 months to complete. The addition of sugar gave the vinegar a good color. Thoroughly ripe, sweet apples were most suitable.

MacGillivray, September 16.

(Average annual rainfall, 19in. to 20in.)

PRESENT.—Messrs. R. Wheaton (chair), H. Ayris, J. Matthews, A. J. Nicholls, H. E. Petras, A. Stirling, jun., H. C. Williams (Hon. Sec.), and one visitor.

SANDY SOILS.—Mr. Petras read a paper as follows:—" There are in our district fairly large stretches of sandy country, which, with a little study and capital, can be brought into very profitable use. There are two distinct classes of sand—deep white, and shallow sand over rubble and clay. On the former the white mallee and narrowleaf predominate. In treating a piece of land of this kind I would select where the scrub is thickest, rolling it in the early summer, and have it all ready for burning by the end of January, the fire being put in the first good opportunity. Ploughing should be done directly after the burn to retain the ashes as much as possible; 3in. is deep enough for a first ploughing on well-burnt land. White sand will grow wheat, and this should be sown first. The next year oats should be sown, and the following year I would plough the land directly after harvest and sow rape, mustard, &c. The fourth year a crop of barley could be put in, and after this it could be left out to grass for a couple of years. Sandy land should be ploughed every third season. Generally at that time the scrub again makes its appearance, and if this is left alone it will soon choke out all grass. Care should be taken that each share is cutting properly. They should be kept well sharpened; when blunt they are too apt to leave strong rooted scrub uninjured. Where sand is shallow over clay wheat should not be sown first. It is better to make fodder paddocks of this particular class of land until the stumps are got rid of; the plough should be put in to reach the clay, and work the sand and clay together, after which the land will grow practically anything. Trenching is, in my opinion, better than lime. Guano super. is a good manure for sand, and I could never notice any difference between this and bone super. or bonedust." Members agreed with much of the paper. Burning late was favored by the Chairman, who left it until March. Shoots were then less trouble in the crop. Oats were considered the best for the first crop. Fallowing might be done the second year, followed by wheat, if anything from 9bush. upwards was likely to be reaped. Guano super. was apparently as good as bone super. for grain crops, particularly barley, and it was cheaper. Mixing nitrogenous manure, such as ammonia, with super. in the proportion of one to five had not shown to advantage. Top dressing during early spring would probably give better results than including it in the sowing manure. An opinion was given that potash would give better results than ammonia or soda with barley. Ammonia was cheaper per unit of nitrogen than soda.

Meadows, September 16.

(Average annual rainfall, 35·52in.)

Present.—Messrs. G. Ellis (chair), Rev. J. H. Williams, J. J. Morriss, H. Thorne, F. Nottage, T. Usher, J. Stone, S. Smith, T. B. Brooks, F. W. Vickery, E. Vickery, W. J. Stone, W. Phillips, H. A. Kleemann.

Leakages on the Farm.—A lengthy paper under this heading was contributed by Mr S. Smith. Failure, in a great many instances, he said, was due in a large measure to carelessness. It was much better to live in one's own cottage than to have a large house heavily mortgaged. Fences should be kept in repair, and feed conserved against dry seasons. Every advantage should be taken of decaying vegetable matter, by applying it to the soil to form humus. Old stumps and logs on grass lands should be fired, the ashes being of considerable manurial value to the soil. The provision of suitable protection for vehicles considerably lengthened their life. They should be washed with rain water, if it were procurable. White lead and mutton-fat applied to the mouldboards of the plough would prevent them rusting. Harness should be kept well oiled. Bran and pollard should be kept in zinc-lined cases; the bags being hung over a wire. An interesting discussion followed.

Meningie, September 13.

(Average annual rainfall, 18·87in.)

Present.—Messrs. W. M. Wright (chair), Scott, J. G. Hastings, J. R. Williams, H. A Martin, H. N. Mincham, W. H. Yates, sen. and jun., S. Yates, and L. D. Martin (Hon. Sec.).

Poultry.—A paper on this subject was read by Mr. H. N. Mincham, who had for a number of years kept Minorcas, Andalusians, Silver Wyandottes, Black Orpingtons, Brown Leghorns, and White Leghorns. The last named, he said, were the most profitable. The best laying strains only should be kept. He made a practice of cutting a few acres of wheat, barley, and oats, and building a stack in which the fowls could scratch. Large quantities of greenfeed should be given them at midday; lucerne was good, and the boxthorn hedge also provided excellent food in addition to shelter. Meat was not necessary if milk could be supplied. The morning feed should consist of bran and pollard mixed with hot milk, and wheat should be fed in the evening. Hatching should take place early in the season, and the pullets should not be forced. Chicks hatched in an incubator would be quite as strong as those brought out by a hen, if they were given proper care and attention. Male birds intended for breeding should not be allowed to run with the hens until they were 12 months of age. They should only be allowed with the hens during the breeding season. Hens for breeding should be carefully selected. Cleanliness was of the utmost importance. Fresh water should be supplied three times daily, and be kept in the shade. Houses should be whitewashed, and shell grit and charcoal supplied. It was advisable to have plenty of nests available. A number of breeds should not be kept. Generally, it paid better to kill a sick fowl than to endeavor to cure it.

Utilisation of Waste.—Mr. J. G. Hastings also read a paper, from which the following is taken:—"There is on every holding a considerable amount of waste material which, if allowed to accumulate, will cause an unsightly appearance, whereas with a little foresight and thought it can be utilised to great advantage. Perhaps to the large landholder the value of refuse may not always appeal. He deals in large quantities, but to the man who is living on a slender income the little things mean much. Ashes, for instance, contain a quantity of valuable plant food in the form of potash, and yet on many places hundreds of pounds of this useful manure is lost in the course of a year; this should be returning wealth to the owner in the form of fruit and vegetables. A large box or tin should be kept handy to receive ashes as they are removed from the house, and at regular intervals they could be run through a fine sieve and then either spread on the land and dug in or stowed away till required. The coals can be used again in the fire or in the blacksmith's forge. At the wood heap, a large quantity of chips accumulate, and in course of time are reduced to a rubbly or powdered condition. In this state they are useful as plant food as well as providing humus for the soil, and if put on in sufficient quantities

keep it loose and so allow the heat and air to penetrate. Clay land especially is greatly benefited by a liberal dressing of this material. All hedge chippings, flower prunings, and weeds should be dug under. When buried in this green state all their valuable properties are absorbed by the soil. Where a horse or cow is kept, the manure should be gathered up daily and either put into a large watertight receptacle or dug under as soon as possible. If left heaped up on the surface the ammonia and nitrogen are lost. The floor of the pigsty should be so constructed as to allow the water and manure to be led off by means of a drain which conveys it to a receiver let into the ground. By this means it can be cleaned daily with very little trouble."

Mount Barker, September 10.

(Average annual rainfall, 30·93in.)

PRESENT.—Messrs. H. N. Bell (chair), Bishop, Moore, Hughes, Daddow, Mappley, Liebelt, Liebing, Schmidke, Hollanby, Fidler, Thomas, Barker, Dr. Scott, and J. E. Smith (Hon. Sec.).

BACTERIA IN THE DAIRY.—The Hon. Secretary (Mr. J. E. Smith, B.Sc.) contributed a lengthy paper on this subject. He described the different types of bacteria, their power of movement, method of multiplication, &c., also mentioning the allied micro-organisms, yeasts, and ferments. Perfectly pure milk, he explained, would not sour; this was occasioned by the growth of bacteria, which caused the sugar to change to lactic acid. The souring of milk in cases had been attributed directly to the influence of thunderstorms, but it was explained that the same atmospheric conditions which brought about thunderstorms stimulated the growth of bacteria. If the milk were kept cool this trouble could be overcome. Continuing, the paper read—" The first question naturally arising is whether there are any bacteria in milk at the time it is secreted by the cow. There is not absolute agreement on this. If the udder of the cow is diseased, the milk may be contaminated, even when secreted. It has long been known that when a cow has tuberculosis in the udder, her milk is practically certain to contain tuberculosis bacilli. It is equally sure that inflamed udders infect the milk with bacteria. When the udder is the seat of the inflammation it commonly produces pus, and this naturally finds its way into the milk. With the pus there are practically sure to be bacteria that are associated with inflammatory troubles. These are usually chain-forming bacteria, hence the presence of large quantities of such bacteria, especially if accompanied by numerous pus cells, indicates a diseased condition of the udder. Such are found in animals having mammitis or mastitis. These bacteria, if in considerable numbers, are certainly detrimental to the health of the persons drinking the milk. The general opinion is, at least under ordinary conditions, that if the cow be in health and her udder not injured in any way, the milk she secretes is at the moment of secretion free from bacteria. Whatever may be the condition of the milk when secreted, it is never sterile at the time it leaves the udder where bacteria are known to be abundant. These probably come from without, entering the milk ducts from the teat, feeding perhaps on the remains of the milk that clings to the passages between the different milkings. How far into the ducts these bacteria extend is again a matter of difference of opinion. Some have held that they are in all the ducts in the glands; others insist that the inner ducts are germ free in normal cows. It is thus very difficult to draw sterile milk from the cow, in spite of the greatest care. By extreme precautions in special tests small quantities of sterile milk have been thus obtained; but these precautions are not practicable in ordinary milking, so the dairyman must recognise that he cannot by any means of milking obtain sterile milk.

Sources of Common Milk Bacteria.—It is quite certain that bacteria get into the milk ducts from the outside. Some have tried to show that they may come from the tissues of the cow, being passed through the gland when the milk is secreted. But while this may be true in case the cow is suffering from some bacterial disease, such as tuberculosis or inflammation in the udder, it is practically certain that this does not occur in normal animals. They are found in the largest numbers just within the teats, where they enter between the successive milkings, and, in lesser numbers, further within the gland. They are in just the position to be largely washed out of the ducts by the first streams of milk drawn. This milk, called the fore-milk, is quite certain to contain more bacteria than milk from the other portions of the milking. During the milking the bacteria may be so thoroughly washed out by the milk stream that the last milk may be quite sterile. Most of the bacteria in the ordinary milk come not from the udder, but from external sources. These sources are several, and may be considered in succession. *The Cow.*—One of the chief sources of bacteria is the cow herself. Her skin, even when kept in fairly good condition, is never very clean and will always hold more or less dirt and dust laden with bacteria. The cow in many poorly kept dairies is, as is well known, rarely, if ever, cleaned; her flanks, tail, and skin become covered with a coating of manure, until the amount of filth attached thus to the animal is surprisingly great. All of this filth is laden with bacteria in large numbers. It is impossible for the cow to move without more or less of it falling from her body, and during the whole process of the milking, by the movements of the flanks, the rubbing of the skin by the milker, and the switching of the tail, there is constantly being shed a shower of such particles from her body. The filth that thus finds its way into the milk-pail consists of almost every conceivable kind of material. Besides excrement there are grass, straws, insect wings, hairs, and almost every other kind of small particles. The nature of this dirt and its amount depend upon the condition of the cow. There will be less on cows during the pasturing season than during their life in the sheds in winter. It will vary much with different foods. Dry foods, like hay, appear to furnish more bacteria in the manure than moist food, and the milk subsequently receives them. It frequently happens that a certain food fed to the cows injuriously affects the keeping of the milk, because the bacteria, which the food furnishes, find their way into the milk from the filth on the cow; for example—the feeding of turnips. *The Air.*—Fresh air out of doors does not contain many bacteria, and if milking could take place in the open, free air this source of contamination could almost be excluded. In a close shed, however, conditions are very different. The motions of the cattle are dislodging bacteria from their skins, which float for some time in the air. Hay, dirt, cobwebs, and other dry dust-producing materials are allowed to accumulate. Dirty straw bedding is another source of air contamination. The general manner of feeding the animals is even a larger source of contamination. If dry hay, or other dry food, is thrown down in front of the cattle, a large amount of dust will arise and spread through the air of the shed. Such dust is crowded with bacteria, many of which are alive and ready to grow. The common practice of keeping the cattle in the same room where they are milked is thus very productive of a large source of air bacterial contamination. The number of bacteria coming thus from the air varies immensely with the conditions of the shed. It is largest during and immediately after the feeding, especially when cows are fed upon dry food. *Milk Vessels.*—Perhaps the most prolific source of milk contamination, so far as numbers are concerned, is found in the bacteria which remain alive in the milk utensils between one milking and the next. Bacteria are not usually killed by short drying. After each milking the pails and other utensils are commonly washed, sometimes, indeed, thoroughly washed with hot water and soap; but no such washing is sufficient to destroy the bacteria which may be in them. After any ordinary washing there will be left clinging to such utensils many bacteria which are ready to develop as soon as fresh milk is added to furnish them with proper food and proper conditions. Every different vessel or utensil with which the milk comes in contact, on its way from the cow to actual consumption, adds its quota of bacteria. *The Milker.*—Of late years it has become more evident that the bacteria from the milker or other persons in the dairy are among the most serious. This is not so much because of the number that may enter the milk from this source, but of their types. In ordinary dairies the milker rarely makes any special toilet before milking, and is liable to perform this task in old, soiled clothes, with no special attempt at cleaning his hands or face. The number of bacteria added to the milk from such a source is, probably, not great and does not add materially to the bacterial content. But in one respect these bacteria assume a more important significance. The bacteria which produce diseases in one animal do not necessary produce diseases in others. Those which produce diseases in cattle, with some exceptions (*i.e.*, tuberculosis), do not usually have the same effect on man. But it is evident that any disease germs that may be present in one man are just the kind that can develop in any other human being. Therefore, the bacteria contamination from human sources is more dangerous to other human beings than any infection from animals. For this reason the bacteria which enter the milk from the milker are liable to be much more dangerous than those which come from any other source.

Effect of Temperature on Numbers.—The number of bacteria in the milk at any subsequent period is more largely dependant upon the temperature and age than upon the contamination. Milk, when fresh from the dairy, even from the slovenly, fifthy dairy, will rarely contain more than half a million or so of bacteria per c.c., and usually a much smaller number. By the time the milk is one or two days old the numbers may amount to 50,000,000 to 100,000,000, or even more. Milk from an ordinary cleanly, carefully kept dairy may have no more than from 10,000 to 50,000 per c.c. at the outset. But this milk, also, in the course of one or two days may have numbers as high as 100,000,000. The number of bacteria present at any time is, therefore, more dependant upon the age of the milk and the method of keeping it, than on the original amount of contamination. Milk which originally contained large numbers of bacteria, if kept cold, will, in 24 hours, show a much lower bacteria count than milk which originally had small numbers, but kept under warmer conditions. This should always be considered in drawing any conclusion as to the number of bacteria in milk. A single illustration will suffice to show the effect of different temperatures upon the numbers of bacteria. A sample of milk was examined for bacteria when fresh and found to contain 6,525 per c.c. It was then divided into two lots, one preserved at 50° and the other at 70°. The fresh milk contained 6,525 bacteria per c.c., that 25 hours old at 50° 6,425 per c.c., and that 25 hours old at 70° 6,275,000 per c.c. Observations seem to show that they do not increase for the first few hours after the milk has been drawn—thus the dairyman has a sufficient time in which to bring the milk into condition for further preservation. The second stage follows with the rise of temperature—all species seem to increase and the numbers amount to 10-20million per c.c., then the lactic acid bacteria seem to gain the upper hand and develop to such an extent that the other kinds are completely replaced. The third stage occurs when the milk has soured and curdled—the acidity is too great, and the bacteria cannot thrive. We may recollect, then, that the lactic acid bacterium acts as a sort of preservative—its rapid development preventing the growth of other species.

Disease Germs in Milk.—There is a wide-spread feeling that the bacteria in milk are closely associated with the distribution of disease—so they may be to some extent, but the commonest bacteria are quite harmless. Buttermilk may contain 500,000,000 per c.c., and is perfectly wholesome. As for the others, four specific diseases, tuberculosis, typhoid fever, scarlet fever, diphtheria, and perhaps cholera may be distributed by milk. Of these tuberculosis comes from the cow, so that it follows that all animals suffering from this complaint should be shut off from the rest of the herd, and their milk destroyed. Pigs and calves, if fed with such milk, may develop tuberculosis. Typhoid fever comes from human beings, and may be passed on to another directly, or, if after recovery, his clothes are not thoroughly disinfected, they may carry the germs of the fever for months; he milks, and the germs may enter the milk pail, and so be passed on to the consumer. Or, owing to the careless handling of matters from the sick room, the germs may be on the hands, the cow is then milked, and the germs pass into the milk, and so to the individual. Discharges from typhoid fever patients may be thrown upon the ground, percolate through the soil with the drainage, or be washed into the water supply—and thence to the cow, and so to the human being. Diphtheria and scarlet fever germs and diarrhœa are spread in a similar manner.

Dairy Methods.—Milk is an ideal medium for bacterial growth. It is a food well supplied with water, and when drawn from the animal, is at a temperature best suited for the most rapid growth of nearly all types of bacteria. The contamination of milk is mostly external to the cow—and the vast majority of these bacteria can be controlled. Therefore we should see that (1) none but healthy cattle are milked; (2) the milk is protected from external contamination; (3) we produce conditions which, as far as possible, prevent the growth of these bacteria. The cow should be examined periodically, and if suffering from any udder disease or tuberculosis, should be separated from the herd and her milk destroyed. The cow shed should allow the freest possible circulation of air—better on rising ground with a good drainage away from any water supply. The cleanliness of the shed is a matter of very great importance. The manure should be removed frequently and taken as far as possible from the shed, and should not be heaped just outside. Dust, cobwebs, &c., are only traps for accumulating dirt, sources of bacteria, thus aiding in the contamination of milk. The bedding, if used, ought to be changed frequently; clean shavings are recommended for this purpose. The place should be whitewashed when required, and water for flushing out purposes used frequently. Milking clothes should be made of washable materials, and sterilized each day. The person of the milker must be kept scrupulously clean, and no one who comes in contact with, or is suffering from any contagious disease, ought to be allowed to approach the milk, cans, cows, or dairy. To milk in the open is an ideal way; if that is not practicable, let the shed be open to the sunlight as much as possible. Do not feed when milking, but afterwards. Cow food always contains bacteria—and of course is moved when the animal is feeding—hence the bacteria are scattered. If the cow is groomed, and dirt and manure moved from its flanks, the milk stands a much better chance of being pure. If long hairs are on the udder, shave them off. For perfect cleanliness, milk cans, &c., should be put in a steam chamber and kept under steam at a considerable pressure for about an hour. This is impossible on the farm, so the next best thing to do is to use boiling water, soap, and soda, dry thoroughly, and then expose the vessels to the sun. The separators require the most attention; then cloths used for any cleansing should be frequently boiled. In milking, the plan of rejecting the first jets of milk is advised, then any bacteria which may have been in the teat are ejected. The udder should not be brushed, but moistened with a damp (not wet) cloth, A covered pail is preferable to an open one, and this should contain some kind of strainer to catch the larger particles of dirt, and keep them from the milk; if cloths are used, they must be boiled daily. Where many cows are to be milked a milking machine can be profitably used, but a steam jet is necessary to ensure perfect cleanliness. If the cows are stripped dry at each milking, the tendency to the development of bacteria in the udder is prevented, and the next milk contains fewer bacteria. The milk should be aerated, and then cooled immediately, and kept cool; this may mean the use of ice, but cold milk keeps infinitely better than warm milk. The use of preservatives in milk is to be condemned absolutely, and I believe in South Australia their use is illegal. If milk is boiled, all the bacteria which fail to produce spores are destroyed; such milk will keep longer than unboiled milk, but the spores will reproduce, develop, and so cause its destruction. This boiled milk has some advantages—it will never distribute any diseases, nor cause diarrhœal trouble, but the "boiled" taste is not pleasant, and boiled milk is somewhat less digestible than raw milk. Many people "scald" their milk—that is equivalent to pasteurizing it—the process being to heat the milk to a temperature of 160° and keep it at that temperature for 10 minutes or so. All the ordinary disease germs are destroyed, as well as the lactic acid bacteria. Expert opinion seems to differ as to whether pasteurized milk is more easily digested than raw milk, but agreement seems to be reached on the point if the temperature has not risen above 140°. Simple sets of apparatus can be purchased for use in the home, in which milk of doubtful purity can be rendered safe to use.

Narrung, September 6.

(Average annual rainfall, 17in. to 18in.)

PRESENT.—Messrs. L. Thacker (chair), G. G. Hacket, L. Bolger, L. H. Mann, T. Barker, F. McNicol, C. H. Metcalf, G. Brodie, E. L. and G. R. Goode (Hon. Sec.).

BUTCHERING.—Mr. L. Bolger read a paper in which he described the method of killing, dressing, and cutting up a beast. It should be yarded at least 12 hours before killing, he said, and it was advisable to rope it, drawing it up to a post so that it could be pethed. When the animal was down, the head should be placed so that the blood would run away freely. After the throat was cut a piece of cane or wire should be worked backwards and forwards up the spinal cord, which would cause the blood to flow freely. It should then be placed on its back, and skinning should be commenced by first taking off the fore legs and then ripping the skin down from the throat to the tail. Then it should be taken from the hock to within 12in. of the tail, care being taken not to cut the hide. After the skin was taken well down both sides the tongue should be taken out, the windpipe released, and the brisket and the H-bone sawn through. After the caul fat was removed the carcass should be raised about 4ft., and the skin removed from the tail and well down the back. The backbone should then be sawn down and the carcass allowed to hang all night. The following morning it should be quartered. The hide should be carefully salted all over and laid out flat.

Uraidla and Summertown, September 1.

(Average annual rainfal, 44·35in.)

PRESENT.—Messrs. H. F. Johnson (chair), E. Hart, E. Hawke, J. Rowe, G. Collett, Fleming, Kessell, Moulds, Cobbledick, Collins, and Prentice (Hon. Sec.).

PIG-BREEDING.—In a paper on this subject, Mr. E. Hart expressed the opinion that the cross between the Berkshire and Yorkshire or Tamworth was the pig best suited to this district. Sties should be built 18in. or 24in. above the ground, to allow of good drainage. The troughs should project from the side about 6in. The sow was capable of breeding at the age of 7 months, and the boar was fit for service at 12 months. However, it was advisable to delay farrowing until the sow had reached an age of 15 months, and the boar should be kept from continued service until 18 months old. Two good litters per annum were sufficient. Gestation lasted for about four months. Old sows were more constant and careful mothers than young. After farrowing, the sow should be fed on warm meal for the first few days. Cocky chaff or short straw should constitute the bedding. The young pigs should be castrated when five weeks old; at six weeks they should be weaned. Regular feeding was essential. Mr. J. Rowe thought pig-breeding in connection with gardening a profitable undertaking. Surplus vegetables made good feed.

STRAWBERRY-GROWING.—Members thought it inadvisable to replant strawberries on land previously under this crop, with the exception of Melbas, not being irrigated.

SOUTH-EAST DISTRICT.

Frances, August 26.

(Average annual rainfall, 20·74in.)

Present.—Messrs. J. McGillivary (chair), G. Holmes, L. McInnes, A. J. Baldock, F. Cooper, T. J. O'Brien, W. Tompkins, W. Jarred, V. Redman, B. F. Feineler (Hon. Sec.), and one visitor.

Seed Wheat.—The Chairman strongly advocated thoroughly cleaning wheat intended for seeding purposes. He described a grading machine, manufactured locally, which was very effective, and could be made at a cost of about 30s.

Cockatoos and Grubs.—Members reported considerable trouble with cockatoos pulling up and eating seed that was just shooting. The use of strychnine, poisoned wheat, or poisoned flour mixed to a paste with wheat and strychnine rolled into it, and sweetened with sugar, was recommended. Some members advocated shooting. A greyish striped, brown to dark-green coloured grub was causing much trouble in the wheat fields. It spent the day under the clods and fed on the wheat plants at night. Rolling was the best means of destroying the pest, and deep furrows ploughed round the paddocks prevented its ingress.

Glencoe, August 11.

(Average annual rainfall, 33·84in.)

Present.—Messrs. A. Dow (chair), J. Dow, H. A. Cameron, G. E. Copping, J. and W. Holloway, J. T. Halliday, F. A. Telfer, and G. F. Ferguson (Hon. Sec.).

Potatoes.—In a paper on the growing of potatoes, Mr. F. A. Telfer said it was essential to have land intended for this crop free of weeds. It was a good idea to skim the land before commencing planting. Only good seed, well looked after, should be planted. A change of seed also was advisable. For early planting Pinkeyes could be put in 24in. apart, with 30in. between the rows. Redskins, 30in. apart and 30in. between the rows, could then be planted; Snowflakes following. The seed should be cut at least every other year. The land should be ploughed to a depth of 5½in. or 6in., the dib being used for planting. Each night the ground should be harrowed to cover the seed in case of frost. It was a good plan to loosen up the soil with a disc cultivator just before the plants showed above ground; this could be followed by harrowing, which would destroy the weeds. Moulding should be done in damp weather, if possible. The Chairman thought skim ploughing early in spring a good idea, but had sometimes found that the potatoes grew just as well if planted under a dry sod. Mr. H. A. Cameron concurred. Last year, very late, he planted some poor seed in dry and hard ground. Opportune rains fell, however, and the result was some of the finest potatoes he had ever grown. Eel worms were likely to be troublesome in tubers planted in land that lay stiff and open. The Hon. Secretary reported that last year he scarified eight rows of potatoes immediately they were up, and left eight rows adjoining for a month. The crop from the former was 13 bags, and from the latter nine bags. Mr. J. T. Halliday had secured best results from grass land during the past two years. Shallow planting seemed best.

Naracoorte, August 9.

(Average annual rainfall, 22·60in.)

Present.—Messrs. L. Wright (chair), A. J. Johnson, W. E. Rogers, A. Pallant, R. A. Jenkins, W. Loller, C. Bray, A. Langeludecke, jun., W. H. Smith, A. Caldwell, J. B. Nolan, and S. H. Shinckel (Hon. Sec.).

Homestead Meeting.—The meeting was held at the homestead of Mr. S. H. Shinckel, and considerable interest was taken in the work being done on the holding. Last year Mr. Shinckel had put in 30 acres with wheat and oats, and drilled in chou moellier seed at the same time. The land was turned up very deep with a disc plough and sown dry with ¾lb. of chou moellier per acre early in May. In June the whole was reharrowed. From this 30 acres he had cut 16½ acres for hay, stripped seven acres for wheat, and six and a half acres of oats were reaped, which yielded 43bush. per acre. Altogether 23 acres were cut with the binder, the other seven acres being dealt with by the stripper. The oats cut for hay yielded about 2¼ tons to the acre, and the wheat for hay about a ton to the acre. The balance in wheat, which was stripped, yielded 18bush. per acre. In the first week in February he put 230 Merino sheep in the stubble and kept them for nine days. The chou moellier yielded a large quantity of feed. On April 22nd he put 150 sheep in the paddock and kept them there for 15 days. For 21 days from May 6th he had 50 sheep in the paddock. The average total of sheep grazed for the four months was 45, or one and a half sheep per acre. He was of the opinion that this fodder did better on soil with a limestone bottom.

Naracoorte, September 20.

(Average annual rainfall, 22·60in.)

Present.—Messrs. W. Loller (chair), W. E. Rogers, R. A. Jenkins, A. Pallant, A. Langeludecke, A. J. Johnson, F. H. Holmes, A. Caldwell, S. H. Schinckel, C. Bray, J. M. Wray, B. O. Henig, and W. H. Smith (Hon. Sec.).

Compulsory Dipping of Sheep.—The suggestion that sheep-dipping should be made compulsory, on which subject the Branch had written a number of Branches south of Adelaide, had been considered by these, with the result that Morphett Vale, Meningie, Tintinara, Longwood, Mount Gambier, Strathalbyn, Monarto South, and Hartley Branches favored the proposal, whilst Kanmantoo Branch opposed it.

Penola, September 29.

(Average annual rainfall, 26·78in.)

Present.—Messrs. H. Richardson (chair), W. Miller, J. T. Williams, J. Warner, A. E. Lampe, J. Alexander, A. H. Strong, L. Peake, and one visitor.

Spring or Autumn Lambs.—Mr. J. T. Williams read the following paper:—"The greater part of the lower South-East is so wet in winter than in many seasons, if the lambs are dropped in the autumn they become very poddy, and are subject to both lung and intestinal worms. They barely exist during the cold, wet months of July and August; in fact, a goodly percentage of them die off, the result being that at shearing time, although marking may have shown 80 per cent., there are then only 70 per cent. to face the shears; and a lamb stunted in the first few months of his life never makes as good a sheep as one that receives no check from the day of its birth. In this wet country the spring lambing has many advantages. More ewes can be carried through the winter months, and not being dragged down by the lambs they come into the spring in good condition, and will give a better return per head of wool. Further, there will not be so much tender wool in the clip from them as from ewes that have lost their lambs during the hardships of winter. At this period of the year the lambs drop right into the sunshine and coming grass. In consequence they get no check. During my term of management on Yallum Estate I have had one part of the flock each year timed to lamb in the spring, and on every occasion they have proved a better crop than those dropped in the autumn. They have been dropped in the latter part of August and September and shorn at the end of November, when they cut from 1lb. to 1¼lbs. of wool (which pays for the shearing). The wool is the only point of loss against the autumn lamb, which returns 3lbs. to 3½lbs., according to the season. Each year I have practically weaned the total number marked, and they do not appear to be nearly so subject to parasites as the autumn lamb, show more growth, and as hoggets they cut more wool. Thus, from my experience in the wet country I would advise the lambing to take place in the spring. But in rich high country the early lamb is undoubtedly the best, because the rich country dries off early in the summer, and leaves no succulent feed to keep a late lamb going during that season of the year, as in the lower country; and the aim of the producer on the rich land is a 'fat lamb,' which can be got off in time: afterwards to fatten the ewes on the spring grass. Whichever lamb one may favor or produce the great factor towards success is to feed them well, as the old saying still stands good, 'Half the breeding goes down the throat.' Do not have two lambs looking for one blade of grass, have grass before the lambs, whether autumn or spring."

Tatiara, August 30.

(Average annual rainfall, 19in.)

Present.—Messrs. M. Sullivan (chair), A. Fisher, A. Wilson, C. Sloude, Miles, Webb Marshall, Harvey, Stanton, Bond, Low, Truman.

Dry Farming.—Mr. Fisher read a paper under this heading, in which the need for systematic fallowing was strongly urged. The results of various experiments in different parts of the world were quoted. Members generally agreed that it was advisable to work fallow well, and recommended harrowing growing crops when they had reached a height of about 8in.

Tintinarra, September 6.

(Average annual rainfall, 18·78in.)

Present.—Messrs. J. Donaldson (chair), C. M. Ives, E. B. Northcott, J. Helling, C. P. Hodge, Taylor, Henderson, Taylor, Kneale, D. T. Kennedy, Kneale, Stead (two), Bell (three), M. F. Hodge (Hon. Sec.), and three visitors.

Farm Gardens.—In a paper on this subject, Mr. J. Donaldson said that, other things being equal, he would choose a site surrounding the homestead for a farm garden. This should be fenced with posts 12ft. apart, 4ft. 9in. out of the ground and 4ft. wire netting buried 3in., two barbed wires being placed above this. One acre enclosed in this way should provide sufficient flowers, fruit, and vegetables for a large household. Carrots, parsnips, trombones, marrows, potatoes, onions, &c., could be grown in addition to a dozen or two of fruit trees and vines. The fruit trees should be planted 18ft. apart and should be well pruned. Vines should be trellised, as there was then less danger of injury from frosts. An abundance of stable manure should be applied to the soil, and care should be taken to plant vegetable seeds at the proper time.

Wirrega, September 3.

(Average annual rainfall, 19in. to 20in.)

Present.—Messrs. H. Exton (chair), F. Meier, W. Fairweather, P. Prime, H. Laurenti, J. Bice, F. Knowling, R. Williams, F. and L. Densley, J. Green, H. Rogers, L. Pitman, L. Cook (Hon. Sec.), and four visitors.

Poultry on the Farm.—Mr. H. Densley read a paper, in which he recommended the White Leghorns for egg production and White Wyandottes as table poultry. Such breeds as White Wyandottes, Black Orpingtons, Plymouth Rocks, &c., were good for the dual purpose. Inbreeding was disastrous to the laying qualities and health of the birds. A rooster of a fresh strain should be mated with four to six of the best hens each year. Galvanized iron houses were best: brush and bags harbored vermin. Fowls given the run of the stables would lay better and require less feed than those closely confined. Breeding should be commenced about the end of August. Chicks hatched in March or April were usually of a good size by Christmas. Pure bred birds were best. The general opinion of members was that a change of blood in the stock was necessary only once in three years. Each male bird should have between 12 and 20 hens.

Shipping Frozen Carcasses.

THE JOURNAL OF AGRICULTURE

Published Monthly.

Subscription, 1s. per annum to residents in South Australia, and 2s. 6d. per annum elsewhere, including postage.

Circulation, 6,500 Monthly.

The Journal contains information of an official character relating to the Agricultural Lands, Stock, and Produce Export Departments. Illustrated articles and paragraphs by Government experts dealing with all branches of agriculture, horticulture, viticulture, pastoral matters, dairying, stock diseases, poultry, etc., are published regularly.

The results of experiments in connection with methods of agriculture, etc., stock and poultry diseases, insect and fungoid pests in South Australia and other lands are recorded, as well as the results of work at Roseworthy Agricultural College.

The experience of members of the Agricultural Bureau is made available to subscribers by the publication of reports of meetings of the Branches, including the more important papers and the discussion on them.

The Inquiry Department of the Journal furnishes replies by Government experts to all questions sent in, and advice is given to beginners in agricultural industries.

The Reference Library of the Department of Agriculture, which contains so many valuable works on agricultural subjects and thousands of bulletins issued by Departments of Intelligence in all parts of the world, is at the disposal of subscribers during office hours.

Applications for enrolment on the subscribers' list should be addressed to the Department of Agriculture, Victoria Buildings, Victoria Square, Adelaide.

POINTS FOR PRODUCERS.

New South Wales Wheat Crop.

It is estimated that this season's wheat yield in New South Wales will be the largest in the history of the State. Last year's crop was a record, 32,475,13bush. having been produced, an average of 14·6bush. per acre. It is not anticipated that the average per acre will be as high this year, but that the increased area under crop will give a higher total yield, which some authorities estimate at 36,000,000bush.

Queensland Wheat Crop.

The Acting Government Statistician has prepared an estimate of the wheat crop for Queensland for 1913, which shows 170,006 acres sown, of which 132,348 is estimated to yield 2,053,783bush. and 17,872 acres to yield 17,037 tons of hay and 19,789 acres cut for greenfeed. The yield last year was 1,973,605bush. of grain from 124,963 acres.

Price of Wheat in England, 1912-13.

The price of home-grown wheat in England during the cereal year 1912-13 averaged 32s. per quarter, a fall in price of 2s. 10d. per quarter compared with 1911-12. On the other hand the average price of imported wheat increased from 35s. 11d. per quarter in 1911-12 to 36s. 2d. in 1912-13. The average declared value of imported wheat in previous years was 33s. 10d. in 1910-11, 37s. 5d. in 1909-10, and 39s. 1d. in 1908-9.

Wheat Production.

In the September number of the *Bulletin of Agricultural Statistics*, issued by the International Institute of Agriculture, the wheat production of France, Hungary, and Roumania is estimated respectively at 87,833,000 quintals, 45,361,519 quintals, and 24,000,000 quintals, or 96·8 per cent., 90·3 per cent., and 98·6 per cent. respectively of the 1912 production. For the total of the following countries, Prussia, Belgium, Bulgaria, Denmark, Spain, France

England and Wales, Hungary, Italy, Luxemburg, Roumania, Russia in Europe (63 governments), Switzerland, Canada, United States, India, Japan, Russia in Asia (10 governments), Algeria (excluding the department of Algiers), and Tunis, the production of this year is estimated at 906,328,681 quintals, or 104·1 per cent. of the production of 1912 (which was 871,044,979 quintals).

Treating Young Pigs.

For three or four weeks after the pigs are weaned, at seven or eight weeks old, skim milk is fed with solid food mixed with it at the rate of about 12lbs. to 15lbs. of milk to 1lb. of grain. This mixture fed sweet and warm provides a moderate change from the sows' milk, and, being palatable, nourishing, and easily digested, produces thrift and highly profitable gains. As judgment dictates, the grain portion of the ration should be increased until the pigs are about three months old and thriving well, when a cheaper ration, such as pasture or green fodder in summer and roots in winter, may be gradually substituted for a part of the milk and the grain. Many of the most successful hog-raisers feed their young pigs very largely on skim milk, adding to it a small proportion of shorts or finely ground oats or barley, with the coarse hulls removed. On many hog-raising farms pigs from 10 to 12 weeks old are turned on clover or grass, when they receive little more than skim milk in addition to what they graze and gather while rooting up the sod. Pigs reared in this way not only put on weight rapidly and cheaply, but they lay the foundation for continuous profitable feeding, and whether for breeding purposes or the bacon market they fulfil the requirements exactly. They develop strong frames and lengthy, muscular bodies, providing an excellent medium for converting a large amount of cheap material that in many cases would be wasted into a highly valuable product.—*Agricultural Gazette.*

Foul Drinking Places.

Drinking from foul ponds and muddy drinking-places can inflict direct harm, because in that way many injurious organisms are introduced, not only into sheep, but into all kinds of animals. In these days, says the *Agricultural Gazette*, it is known that the harm done by worms is much greater than was supposed not many years ago, and there is a general desire to keep them in check by frequent drenching. Still, prevention is always better than cure, and when the foul water is proved to be a danger, care of drinking-places should be more rigorously observed. There is the special reason for prevention in the fact that several of the most injurious verminous attacks have not been found to be curable.

What Have You Learned?

"Experience instructs fools" is the translation of a Latin proverb with which one of the contributors to the topic this week begins his essay. It is generally conceded that where a man can profit by his experience he is in a rather sane state of mind and is getting along very well. In fact if we look around us the fact that comes home most forcibly is the tremendous numbers who pay no attention to the knocks of hard experience. but merely stand up to take another blow in the same place. What have you learned from past experience in farm management? The many who took an interest in the topic this week were unanimous upon one point, that thorough cultivation pays even to the sacrifice of a number of acres. The majority found they got larger crops from manured land. These are to all purposes established facts, yet how many farmers are ready to take every chance on poor cultivation in order to get in a larger acreage. For some years we have not had a season that brought home the truths of "thorough cultivation for sure crops" as we have had this year. Poorly cultivated and weedy land can be picked out anywhere this year; the past two seasons have to a large measure covered up inferior farm work, but this year it is bare.—*Farmers' Advocate.*

Chickens and Electricity.

Electricity has made rapid strides, but perhaps the most extraordinary development is in regard to poultry rearing. Eggs hatched in incubators sometimes yield a percentage of weak chicks, so that many young ones die during the first few days. If, however, electric currents are applied to the chicks, these have such a stimulating effect that they not only preserve the life of weakly chicks, but enable them to gain weight on their normal amount of food, becoming in about two months as heavy as chicks grown for three months in the ordinary way. It is estimated, says the *Poultry Keepers' Journal*, that a farmer could, by the application of electricity to his poultry farm, produce nearly 50 per cent. more chickens per annum at a cost which works out very much lower than the cost of producing the electrification. Indeed, the possibilities of electricity as applied to agriculture and farming are almost endless, and agricultural experts are watching with the keenest interest many experiments which are at present being made throughout the country on these lines.

Lucerne Soil.

Doubt as to whether a particular soil is suitable to lucerne deters many farmers from sowing this valuable crop. A circular issued by the University of California, says the *Agricultural Gazette*, gives some information upon this point. Lucerne, it is stated, is a deep-feeding plant, sending its tap-root far down into the soil for nutriment, and a deep, well-drained, moderately heavy loam, with no hard pan between the surface soil and the water-bearing stratum, is to be preferred. The best lucerne fields in California are on such soils. But short of the maximum of advantages the crop flourishes satisfactorily in many cases on light sandy soils and heavy clays. Soils containing water close to the surface are to be avoided, as in these the tap-root is likely to decay; therefore good natural or artificial drainage is essential to success with this crop. It is simply stated that most of the Californian soils are well supplied with the mineral plant food necessary for success with the crops, but that in many there is a deficiency of humus. It is suggested that to supply organic matter a winter green crop may be grown and ploughed in early in the spring before the lucerne is sown. This would be only a makeshift for a good dressing of farmyard manure, applied some time before the lucerne needs to be sown, in order that the ploughing may be done in time to allow of the land being brought into good condition by frost. In preparing the land the hard pan caused by repeated ploughings should be broken. That is to say, the land should be subsoiled. The circular recommends drilling lucerne seed on naked land, strongly condemning the plan, often adopted, of sowing it in a corn crop. The seedbed should be firm.

Balanced v. Unbalanced Rations for Dairy Cows.

With a view to demonstrate the loss which may be sustained by dairymen who supply their cows with unbalanced rations, the Department of Dairy Husbandry, University of Illinois, carried out the following experiment:—Two lots of nine cows producing practically equal quantities of milk and butterfat were treated for 131 days in every way alike, except in the rations fed. The treatment for several months previous to the commencement of the experiment period had been the same for all the cows. The rations supplied were as follows:—

	Lot 1.		Lot. 2.
Maize silage	30lbs.	..	30lbs.
Clover hay	8lbs.	..	5lbs.
Gluten feed	4⅔lbs.	..	3lbs.
Ground maize	3⅓lbs.	..	8lbs.

The ration fed to lot 1 was a well-balanced one for cows giving 40lbs. of milk daily, and had a nutritive ratio of 1 : 6; while that fed to lot 2 was deficient in protein, and had a nutritive ratio of 1 : 11. The following conclusions were reached:—The quality of the ration affects the physical condition of the animal, and the physical condition vitally affects consumption and production. The cows on the unbalanced ration lost greatly in flesh during the test, and their subsequent production was reduced. Lot 1, which received the balanced ration, produced approximately one-third more than lot 2 receiving the unbalanced ration. Thirteen cows on a ration with a nutritive ratio of 1 : 6 produced as much as 18 cows on a ration with a nutritive ratio of 1 : 11. Because of the lack of protein in the ration fed to lot 2 the other nutrients were not used to the best advantage. This shows in a striking manner that an excess of carbohydrates cannot be made to take the place of a deficiency of protein.—*University of Illinois Agricultural Experimental Station Bulletin* 159.

Imports of Grain into United Kingdom.

The imports of wheat into the United Kingdom during the cereal year September 1st, 1912, to August 31st, 1913, amounted to 26,500,565 quarters (of 480lbs.), these being greater by 2,391,000 quarters than the imports of 1911-12, and by 2,984,000 quarters than the imports of 1910-11. Including the produce of the home wheat crop of 1912 (says *The Journal of the Board of Agriculture*), and converting the imported flour into an equivalent quantity of wheat, the total quantity of wheat available for consumption in the United Kingdom was 37,324,750 quarters, compared with 35,472,600 quarters in 1911-12, and 33,854,000 quarters in 1910-11. In these amounts seed is included, but not stocks carried over.

Tuberculin Unions.

An example of what can be done is afforded by the tuberculin societies which have been formed in various parts of Denmark. The Tuberculin Union of Remkold will serve as an illustration (says the *Journal of the Board of Agriculture*). It was founded by Mr. N. O. Neilsen, veterinary surgeon, in 1905. Its rules are briefly as follows :—1. To become eligible for membership the farmer must have had his cattle inoculated with tuberculin. 2. He must divide his stock into two herds—one reacting, the other non-reacting. 3. He must keep the herds in distinct cowsheds, and provide them with separate pasturage and attendants. If possible, they should be isolated on different farms. 4. He must thoroughly disinfect the cowsheds, troughs, and all utensils used by the non-reacting herd. 5. He must have his healthy herd inoculated with tuberculin every six months. 6. He must remove the calves of the reacting herd and feed them either on milk from the non-reacting herd or on pasteurised milk. 7. He must not add any calves to the healthy herd except those which have given non-reacting symptoms to the tuberculin test made when the calves are some days old. 8. He must not add any cattle bought at a market to the healthy herd without previously submitting them to the tuberculin test. 9. He must sterilise the milk of the tuberculous cows before using it as food, either for man or beast. 10. He must immediately get rid of the reacting animals that show clinical symptoms of the malady. The union started with 29 members, and has now 155. Of the 155 herds of cattle 91 were healthy when their owners joined the union, while the remaining 64 were reacting. At present 135 of the herds are non-reacting, and only 20 reacting. The members have now 2,947 healthy cattle all told. Only two of the members have large herds of cattle—they have 800 and 300 head respectively. The other members have only 40 head or less; many of the members are small farmers possessing only three or four acres. Of the two large herds one is thoroughly healthy, while the one with 800 cows includes 80 reacting cattle.

Livestock Insurance in France.

The minimum premium which may be charged by the local livestock insurance societies in France is 1 per cent. of the value in the case of cattle; 1·6 per cent. in the case of horses, asses, and mules; and 2·5 per cent. in the case of brood mares: but in order to guard against the local societies charging premiums which are not sufficient to cover losses, societies having a deficit on their working are bound to raise the insurance premiums to an amount sufficient to cover a loss equal to that of the average of the three preceding years. The premium, however, must not exceed 2 per cent. of the value in the case of cattle; 3 per cent. in the case of horses, asses, and mules; and 3·5 per cent. in the case of brood mares. The three classes of animals must be kept quite distinct with regard to premiums and calculations of losses.

Families in Town and Country.

From the sixth volume of the Census of England and Wales, taken in 1911, it appears that the average number of persons per family has declined from 4·62 in 1911 to 4·51. This presumably means the number in a family resident in the house of the parents at the time of taking the census. The average is lowest in counties which are mainly agricultural, and highest in the mining districts, while that of large towns is between the two. This requires explanation, as it is surprising. It might have been supposed that the younger members of a country village family would stay in their homes longer than those of townsmen, whose work is more likely than work on the land to shift its location. But migration to towns and emigration take away many lads and young men, while country girls more generally go out to service than those of towns or the mining districts.

Zinc Salts in Soil.

Zinc salts, especially the nitrate, if present in the soil to an amount supplying less than 0·02 per cent. of zinc, have a stimulating effect; larger amounts were found to have a toxic effect. Zinc exercises only one-tenth the toxic or stimulating influence that lithium does. Lead, when present to the extent of 0·03 per cent., does not possess any toxic influence upon vegetation, and when this amount is given in the form of the nitrate a stimulating effect is observed. With regard to the influence of *lime and magnesia* on wheat, it is concluded that this plant may benefit from the addition of magnesia to a soil poor in that material, so long as the amount of magnesia does not exceed that of lime.—*Nature.*

Imports and Export of Fruits, Plants, Etc.

During the month of October, 1913, 17,236bush. of fresh fruits, 6,217 bags of potatoes, 226 bags of onions, 164pkgs. of swedes, and 56pkgs. of plants, seeds, and bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910; of these, 3pkgs. of plants, seeds, and bulbs were rejected, and 198bush. of Queensland bananas were destroyed, being over-ripe. Under the Federal Commerce Act, 1,200 cases of fresh fruits, 238pkgs. of honey, 1,130pkgs. of dried fruit, 39pkgs. of preserved fruit, and 6pkgs. of jam were exported to oversea markets during the same period. These were distributed as follows:—For London, 225pkgs. of honey, 401pkgs. of dried fruit, 1pkg. preserved fruit, 2pkgs. of jam, and 5 cases of oranges; for Canada, 585pkgs. of dried fruit; for Germany, 9pkgs. of honey; for South Africa, 128pkgs. of dried fruit, 7pkgs. of preserved fruit, 4 cases of jam, and 3pkgs. of honey; for India and the East, 31pkgs. of preserved fruit, 6pkgs. of dried fruit, and 1pkg. of honey; for New Zealand, 832 cases of oranges, 363 cases of lemons, and 10pkgs. of dried fruit. Under the Federal Quarantine Act, 874pkgs. of plants, bulbs, seeds, nuts, &c., were examined and admitted from overesa markets.

Camel Team, Oodnadatta.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

Stock Inquiries.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"G. DeC.," Dingabledinga, asks about the common round worm of the horse (*Ascaris megalocephala*).

Reply—These worms lie in the lumen of the small intestines, and a good way of getting rid of them is to prepare the horse with bran mashes for 48 hours and then administer a five or six dram aloes ball. The worms will come away when the purge acts. Afterwards give daily in the food sulphate of iron 1dr., sulphur 1dr., saltpetere 1dr., salt 1dr.

"G. F. B.," Kingscote, K.I., asks if the contents of a bottle labelled "Fowler's Solution, Poison," are intended as a worm medicine for horses as recommended.

Reply—Yes. Fowler's solution is a liquid which contains four grains of arsenic to the fluid ounce, two tablespoonfuls. This is the maximum safe dose for a horse, and the solution is a very convenient way to administer it accurately by putting the two tablespoonfuls on bran or chaff. It should be given once daily for a fortnight, left off for a fortnight, and repeated for another fortnight. Other inquirers will oblige by noting this reply.

"O. W. D.," Lameroo, has a foal three weeks old which, after a little trouble at birth, swelled in one knee and later in the other side hock.

Reply—The description is of a case of joint evil, which is an accompaniment of navel ill, although that organ is not mentioned in this case. Germs are absorbed during life in the womb, and abscesses result, not only in the joints but in organs such as the liver. Unless the foal is valuable or a pet, destruction would probably be the most economic method of dealing with it. If, however, treatment is desired, it should receive daily 1oz. of 5 per cent.

sol. acetozone (Parke, Davis, & Co.). The abscesses should be opened and the pus cleaned out, then the cavity should be syringed daily with 20 per cent. sol. of the same drug, which is expensive, but about the only one which has a good effect.

" A. P. S.," Maitland, has a horse with canker of the foot of three years' standing, which he has treated with formalin. This has kept the trouble in check, but he wants to know prospects of a cure.

Reply—A cure is not likely. Your line of treatment has been good, and if you are not tired, it would be interesting to try the following :—Use your local application as before, occasionally applying a few drops of pure creosote. Give two tablespoonfuls of Fowler's solution of arsenic in the food once daily for a fortnight; stop 14 days, repeat 14 for a month or two, and note if any alteration occurs in the feet. Procure 2ft. of rubber cord as thick as a pencil and wind tightly round the pastern. At first the horse will not stand more than 10 minutes morning and evening, but the time can be gradually increased to two hours. This often is most successful.

" W. H. W.," Renmark, has a cow which has small pimples on the teats. These burst in a few days and discharge a thick fluid which dries up to a scab and leaves a scar when it falls off. The cow seems in good health and had nothing of the sort before ; she was yarded with another showing the same symptoms.

Reply—This is a very good description of cowpox. Treatment.—Dose with Epsom salts ¾lb., powdered ginger ½oz., in a quart of warm water. Wash the teats with soapsuds, and after rinsing apply daily some of this lotion :—Tincture rhus. tox, 20 drops ; glycerine, 1oz. The disease runs a regular course.

" T. B. B.," Clarendon, asks symptoms of Cape tulip poisoning n a dairy cow.

Reply—Bloating, distress, diarrhœa, loss of consciousness. Treatment.—Stimulants (brandy), purgatives (Epsom salts or oil). A veterinary surgeon would be able to administer physostigmine and other remedies if called in time.

" M. A. N.," Wilkawatt, has a horse which had an eye injured by a piece of hair ; the eye has turned yellow, with matter under it. An ulcer has formed on the front of the eye (cornea), and most probably the horse will lose the sight.

Reply—Treatment :—Hang a cloth over the eye from the forehead-band and wet it three times a day with a little of this lotion—Tr. calendula, 1oz. ; methylated spirit, 1 pint ; water, 1 pint.

" W. L. McD.," Lameroo, has a horse with a tender swelling above the front fetlock. This has been in existence over four months. The swelling is very tender and the horse lame.

Reply—Apparently a strained synovial sheath of the extensor tendon, possibly injury to bone beneath. Treatment—Rest the horse let cold water trickle on to the place for an hour or two a day for a week or so; then, if tenderness has decreased rub in every day a little oleate of mercury, 5 per cent.

Whyte-Yarcowie Branch Agricultural Bureau reports a case of bloodworms in the purse of a colt, and seeks information.

Reply—(1) The appearance of these worms in the belly cavity is well known to the department, and is of frequent occurrence. (2) Local remedies will do no good. The worms must be attacked through the blood, with arsenic and quinine. The dose of arsenic for a yearling is a teaspoonful of Fowler's solution daily for a fortnight; of quinine 10 grains, or as much as will heap up on a sixpence. Both to be given in food. (3) The animal may be treated before the castration wound has healed or after. (4) The fact that it has had only well water emphasises the danger of having an accumulation of dung in the foal yard.

"E. P. Y.," Kercoonda, asks about a growth below a horse's hock, which has been removed once but recurs and bleeds when scratched; brown and hairless, about as big as a pigeon's egg.

Reply—Probably a neoplasm. Remove as before and sear well with red hot iron. If the growth appears to be reforming as the wound heals, make a thick paste with Cooper's dip and lard or vaseline, and apply with a stick once a week.

"G. R. H.," Murray Bridge, reports a case of sanding in a horse on dandelions, and asks for treatment.

Reply—Keep the animal off the dandelions, which nearly always sand a horse, and give a pint or two of new milk, with or without a pound of honey. Repeat if necessary in a week.

HORTICULTURE.

(Replies supplied by Mr. G. Quinn, Horticultural Expert.)

"W. R. C.," Berri, forwards specimens of a beetle said to be ringbarking branches of young apricot trees. He asks for identification.

Reply—The insect is a weevil beetle, belonging to the *Curculionidæ*, and known as *Polyphrades longipenius*. It is an indigenous insect, which has migrated from the eucalyptus to the apricots. If sufficiently numerous to warrant it, spray the trees with arsenate of lead, 1lb. in 10galls. to 20galls. water.

"F. H.,' Ramco, asks—"Would walnuts make a good breakwind; if so, how close should they be planted and the best variety to plant"?

Reply—Walnuts are not recommended as a wind break, as they themselves suffer much from the battering of hot winds, particularly in hot dry localities.

"B. J.," Wilmington, asks how to raise native or wild peach.

Reply—The native peach (*Santalum acuminatum*) is raised from the fresh stones or pits. They may be sown in pots or tins, and put out into the garden later without disturbing the roots. Most hard seeds of this character, however, germinate better if heated, say, by boiling water being poured over them, or better still, being buried an inch or two under the pulverised soil and kindling a fire over them.

"J. C.," Houghton, inquires as to method adopted in raising pears from seed, and what is the best commercial variety of passion fruit.

Reply—The seeds of most cultivated pears do not germinate well, hence those from coarse kinds such as Chaumontelle should be taken. The nurserymen import their pear seeds from France, where they are saved from certain suitable kinds. They should be sown in autumn in drills, in well tilled land, and covered about ½in. to ¾in. deep. The seedlings are very slow of growth and form merely a spur-like shoot the first year. *Passion Fruit.*—There is only one kind of passion fruit of commerce, that produced by *Passiflora edulis*. This may be grown from the seeds extracted from fruit imported from New South Wales by our fruit merchants. Sow the newly extracted seeds when freed of pulp in well-drained boxes in the finely prepared soil, covering them about ¾in. deep and pressing the soil firmly upon them. The spring time and early summer season is the best time for sowing.

Carting Grapes.

AGRICULTURAL EDUCATION.

A SPLENDID GIFT.

All those interested in the welfare of South Australia, and particularly in the advancement of agriculture in the State, will heartily appreciate the patriotism and munificence of Mr. Peter Waite in donating his residence, "Urrbrae," and grounds, for the purpose primarily of agricultural education. The announcement of the gift was made by the Premier (Hon. A. H. Peake, M.P.) in the House of Assembly, on Tuesday, October 14th.

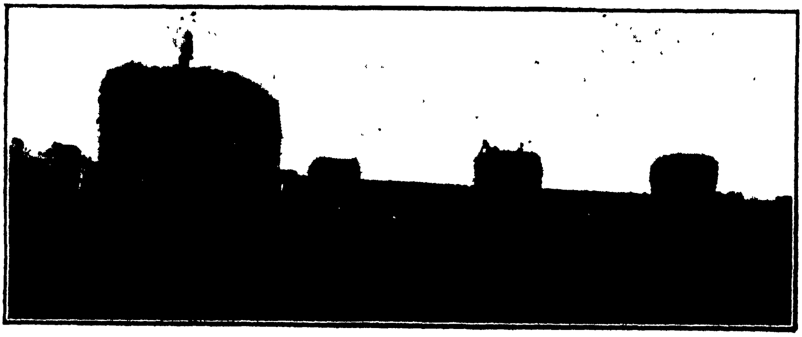
Mr. Peake said he desired to make a statement that would be of interest to the House and the public generally. One of their generous citizens (Mr. Peter Waite) had proposed to make a gift in the interests of agricultural education and of public recreation. (Applause.) The gift was in two parts—one to the Government and the other to the Adelaide University—but they could be regarded as one complete proposal. It was particularly gratifying to him, as it marked the consummation of one of the aims which the Government of 1909 had included in its programme, and also because it gave effect to one of the recommendations of the recent Education Commission. Prior to the publication of the Commission's report, and without a knowledge of its intentions, the Commissioner of Crown Lands was in communication with Mr. Peter Waite, who desired to make the gift in question for the best possible purpose; and, with the Commissioner, he visited the Agricultural High School at Ballarat, and was there confirmed in his desire to further agricultural education. The proposals were contained in a letter received from Mr. Peter Waite, dated October 3rd, in which the donor said he had offered Urrbrae house and 134 acres of land to the University, half of the land to be available for agricultural studies and the balance as a public park. He had also offered the Government 114 acres of land for an agricultural high school. The property was situated between Glen Osmond and Mitcham, and was within four miles of the G.P.O. He did not like to put a value on it, but it probably represented between £40,000 or £50,000. The land for the agricultural high school was ready for immediate occupation. The only condition attached to the gift was that the University and the estate should not be liable for succession duties when the property fell into its possession. The Premier then read the following correspondence, in which the gift and the conditions attached to it were outlined:—"Adelaide, October 3rd, 1913. Dear Mr. Peake—Following upon our conversation of August 30th last, I have now arranged to hand over to the University of Adelaide my Urrbrae house and grounds, embracing an area of 134 acres, half of the land to be available for the University for agricultural and kindred studies, and the balance as a public park under their control. I enclose copy of letter which I am to-day sending to the Chancellor of the University. I now formally offer to the Government of South Australia part section 250, hundred of Adelaide, containing 114 acres for the purposes of an agricultural high school. This land adjoins Urrbrae. In coming to the decision to make this offer I have been much influenced by the wonderful work our agriculturists and pastoralists have accomplished hitherto in face of the very heavy odds they have had to meet. With comparatively little scientific training they have placed our wheat, wool, and fruits in the highest estimation of the world; our sheep have been brought to such perfection that they are sought after, not only by all the sister States, but by South Africa; our agricultural machinery has been found good enough even for the Americans to copy; and our farming methods have been accepted by the other States as the most up-to-date and practical for Australian conditions. We have now reached a point when it behoves us to call science to our aid to a greater extent than hitherto has been done, otherwise we cannot hope to keep in the forefront. It seems to me that our manufactures must soon overtake the requirements of the Commonwealth, and that it is to the land we must look to occupy the coming generations. The only condition I wish to make in regard to the two gifts is that they are contingent only upon the Government undertaking that neither my estate nor the University shall be called upon to pay succession duties thereon. I would like to see the agricultural high school under the control of a board, which might be constituted as follows: Two representatives selected by the Government, and one each by the Royal Agricultural and Horticultural Society, the University, and Elder's Trustee and Executor Company, Limited. This wish, however, is not put forward as a condition of the gift. Further, I hope that some arrangement will be made for those boys who distinguish themselves at the agricultural school to be attracted to the higher work which will be done in the scientific schools of the University. The land for the agricultural high school is, as you know, ready and available for the commencement of operations at any time should my offer of it be accepted. Yours faithfully, PETER WAITE. The Honorable the Premier of S.A., Adelaide."

The following letter had been sent by Mr. Waite to the Chancellor of the University:—"Adelaide, October 3rd, 1913. The Right Honorable Sir Samuel Way, Bart., P.C., Chancellor of the University of Adelaide, Adelaide. Dear Sir Samuel—It appears to me that we are approaching a point in the history of the State and Commonwealth when our manufactures will more than keep pace with the local demand. Our population will, however, continue to increase, I hope, more and more quickly, and the natural outlet for the energies of our rising generation appears to me to be in producing wealth from the land. Our State has hitherto done notably in all branches of agriculture and the allied arts, and largely without scientific direction and education. In the future competition threatens to be so keen that we must equip our people in the best possible manner. In the belief that such sections of the University work as agriculture, botany, entomology, horticulture, and forestry can be better dealt with upon such a property as Urrbrae than at North Terrace, I now desire to offer as a gift to the University the Urrbrae estate of 134 acres, for the following purposes, viz. :—(1) The eastern portion, say 67 acres or thereabouts, with the buildings thereon, to be used for the purposes above outlined, interpreting them in their widest sense. (2) The remainder, say 67 acres or thereabouts, to be a public park under the control of the University ; but if it be thought advisable I would be quite willing that 10 acres or 15 acres, or such area as might be found necessary, should be used as a students' sports ground. When the University authorities have considered this matter I will be pleased to know their decision, and if my offer is accepted the title can be at once transferred to the University, subject to the life tenancy of my wife and myself and of the survivor of us. I am making it a condition with the Government that the University shall not be liable for any succession duty when the property falls into your possession. Yours faithfully, PETER WAITE."

OFFER ACCEPTED.

The Premier said the University Council immediately accepted the munificent offer, and viewed Mr. Peter Waite's action as highly patriotic. The Government regarded the offer to it as equally important. All the members of Mr. Waite's family were agreed in the proposals. (Applause.) Mr. Waite had done a great deal in developing the important pastoral interests in the interior. No name was better known than was his in that respect. (Applause.) It was gratifying to know that he was still interested in its further development. The fact that the University School and the Agricultural High School would be side by side should conduce to the success of both, as well as to economy in their working. The proposed Fullarton tramway terminus would extend to both properties, which were within four miles of the G.P.O. Members of that House would be able to appreciate the great value of the gift. The land altogether comprised close on 250 acres, and was in the County of Adelaide. In itself it was very valuable. Not only was there the land, but a mansion in addition. It was a joint gift to the State and the University. It would enable the Government to give effect to one of the recommendations of the Education Commission, which was that there should be an agricultural high school near to the city, so that boys in Adelaide who had no other chance of getting out into the country could go there and learn the elements of farming, and possibly a good deal more. Then they would be better fitted to go into the country and exercise their faculties in their own interests as well as those of the State. It would draw away boys whose outlook now was nothing but a city life. Mr. Waite was a gentleman who, by a life's work, had done a great deal, chiefly in association with the late Sir Thomas Elder and other gentlemen, whom they were all proud to remember, in developing the important pastoral interests of the interior, and who had rendered great service by giving of their wealth to benefit their fellow citizens. Mr. Waite's name would go down honorably associated with those gentlemen as one who had striven successfully to do good in the land of his adoption. (Applause.)

At a meeting of the Council of the University held on October 9th, it was resolved that the following letter expressing the Council's appreciation of his generosity should be forwarded to Mr. Waite:—"October 10th, 1913. Dear Sir—Your letter of the 3rd instant to the Chancellor, offering one-half of your Urrbrae estate to the University for promoting the study of agriculture and allied subjects, and the other half for the purposes of a public park under the control of the University, was laid before a special meeting of the Council on the 9th instant. The Council unanimously decided to accept your munificent offer, subject to the conditions set forth in your letter. They have no doubt that the object you have in view will be of immense value to the State of South Australia, and that Urrbrae is pre-eminently adapted for carrying out your plans. The prospect of founding a school of agriculture under auspices so fortunate and conditions so favorable is viewed with very great satisfaction by the Council. We are desired to convey to you the Council's most cordial thanks for your noble benefaction, and to assure you that your generosity will be gratefully remembered for all time by the public of South Australia, and in particular by the members of the University of Adelaide.—We are, dear sir, yours sincerely, S. J. WAY, Chancellor, WILLIAM BARLOW, Vice-Chancellor. Peter Waite, Esq., Urrbrae, Glen Osmond."



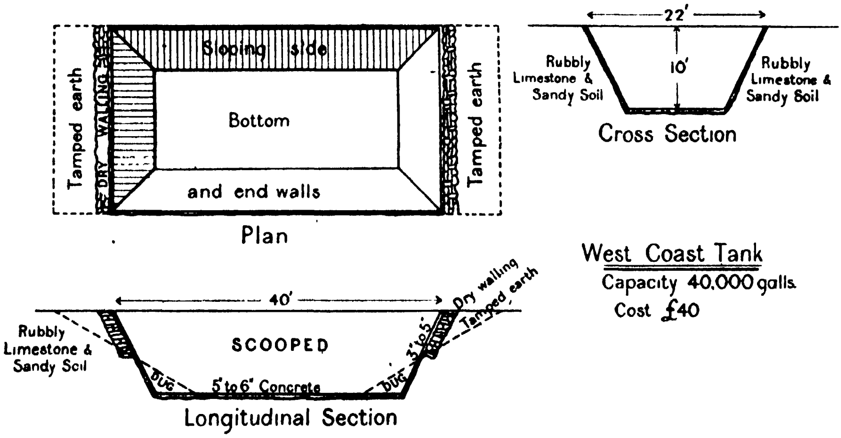
Haymaking.

CHEAPLY CONSTRUCTED TANKS.

In reply to inquiries for the details of construction of the cheaply constructed tanks referred to in his address to the Agricultural Bureau, the Government Geologist (Mr. L. Keith Ward, B.A., B.E.) has furnished the following diagrams and notes :—

CEMENT TANKS.

The tank illustrated on this page is typical of those constructed by farmers in the more sandy portions of Eyre's Peninsula to the east and north of Streaky Bay. In this district the problem of water conservation is a very difficult one, as the great majority of the wells sunk have been failures, while the porous nature of the soil precludes the use of unlined excavations for surface conservation.



Plan

Cross Section

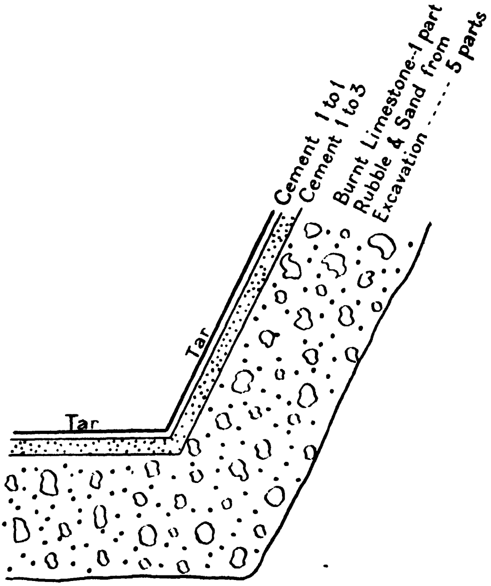
Longitudinal Section

West Coast Tank
Capacity 40,000 galls.
Cost £40

Generally speaking the excavations made show a sandy material, or sometimes a very soft sandstone and a limestone rubble lying beneath the surface soil and mixed with sandy material. A site for a tank is chosen, if possible, at the foot of a steep slope, often where a well-beaten road provides a good gathering ground and run for the water. In some cases the catchment is cleared of soil to the underlying limestone to provide a better run off.

The tank figured was excavated with a tank scoop and bullocks, but the toe of the sloping ends had to be dug by hand and the earth packed behind a dry stone wall of limestone. The sides and ends were sloped to permit of the concrete being laid in place with a shovel, and to do away with the necessity of using forms or moulds. The concrete was made of one part of locally burnt lime to five parts of sandy rubble got from the excavating of the tank. The walls vary in width from 3in to 5in., the bottom being slightly thicker. The concrete was faced with two coats of cement, one to three and one to one of sand respectively, and finally tarred. It was then roofed with brushwood and fenced to prevent stock from falling in.

The owner gave the cost as £40, and stated that two men could construct the tank in a month. Cement is used throughout, where the materials are not available for making lime, in proportions varying from one to seven to one to nine.



Detail Section

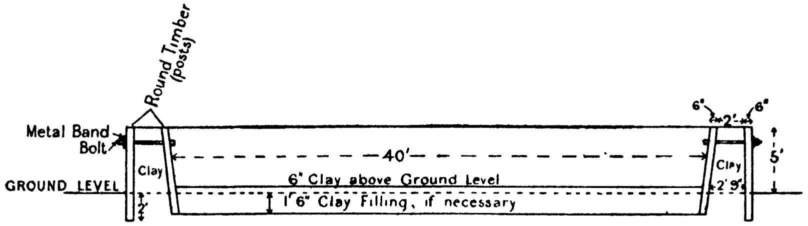
It should be clearly understood that this frail type of tank is only suitable for sandy ground, as the presence of any considerable proportion of clay will rack the masonry to pieces owing to the expansion and contraction of the clay with the changes of the weather. Subject to this limitation, the tank will be found to be efficient and to have the merits of simplicity and cheapness. For men of limited capital the construction of such tanks is wiser than the expenditure of an equivalent amount in well-sinking in districts where a wide spread distribution of useful underground water is known to be absent.

MUD TANKS.

The " mud tanks " which are used in the eastern and north-western parts of the State have been devised to take advantage of the local supplies of building materials in localities which are remotely situated, and where the cost of transport prohibits the purchase of metal tanks.

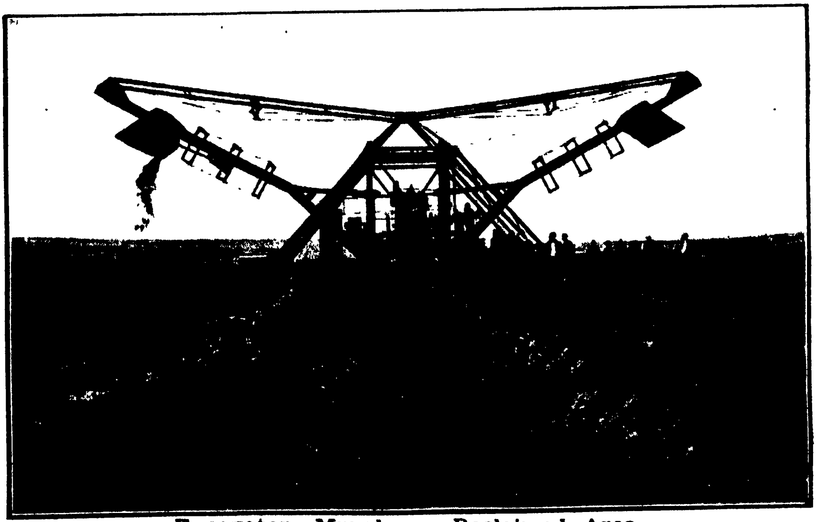
The only materials employed are round timber posts, clay, and an iron strap or band which encircles the tank like the hoop round a barrel, being fastened to the timber by long bolts. Angle iron is sometimes used for the band encircling the timber. The sectional diagram explains the construction of one of these tanks.

There are two circles of posts, those in the outer circle being vertical and sunk 2ft. into the ground, while the posts of the inner circle are slightly inclined and are not quite so deeply buried. The bottom is excavated, if necessary, to a depth of 18in. and the excavation is filled with clay. In any case a layer 6in. deep of clay is placed at the bottom of the tank. The space between the two rings of posts is filled with clay, which is rammed hard into position. Should this clay crack and open during periods of disuse it can very easily be moistened and rammed tight again when the tank is to be used once more.



Mud Tank. -Capacity, 35,000galls. ; cost, £40.

In many cases these tanks are surrounded on the outside with clay, which is heaped against the outer ring of posts and rammed down. In other cases the tanks are more deeply buried than the example shown in the diagram.



Excavator, Mypolonga Reclaimed Area.

AUSTRALASIAN FRUITGROWERS.

TENTH ANNUAL CONFERENCE.

The Tenth Annual Conference of the Australasian Fruitgrowers was opened by the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), in the Exhibition Building, on Wednesday, October 22nd, and was continued with intermissions, when various functions of a social nature were held, until the evening of Friday, October 25th. The President (Mr. E. Hannaford) presided, and the following delegates attended :—Vice-president, Mr. J. Tully (Victoria); Queensland—Messrs. H. J. Kipping and T. I. Reaney; Western Australia—Messrs. M. H. Jacoby and W. E. Dempster; New South Wales—Messrs. H. J. Rumsey, E. K. Wolstenholme, and W. E. West; Victoria—Messrs. A. F. Thiele and J. H. Lang; Tasmania—Dr. Benjafield and Messrs. L. M. Shoobridge and E. R. Shields; and South Australia—Messrs. G. R. Laffer, H. E. Pitt, and C. T. Fisher. The official visitors were—South Australia—Mr. G. Quinn (Horticultural Instructor); Western Australia—Mr. J. F. Moody (Fruit Industries Commissioner); Victoria—Professor D. McAlpine (Commonwealth Pathologist) and Mr. J. G. Turner (Chief Horticultural Officer); and Tasmania—Mr. J. Osborne (Fruit and Forestry Expert).

THE OPENING SPEECH.

The Minister, in the course of his opening speech, after welcoming the delegates, said—Those present have had the privilege of seeing some of the work we are doing on the River Murray to bring into profitable use, by means both of reclamation from the river and of irrigation, land that is eminently suited for closer settlement. The high land which it is proposed to work at Mypolonga, and which I believe is eminently suitable for the growth of citrus trees, stone fruits, and vines is typical of a vast area of land in this State adjoining the river, which only requires to be irrigated to produce in abundance. Given a market for the produce that could be raised on such land, I think that I am within the mark in saying that there is in this State over 100,000 acres of such land which can be made available to fruitgrowers.

AREA AND OUTPUT.

"I find on consulting the Commonwealth official statistics that the total area under orchards, vineyards, and market gardens exceeds 300,000 acres, and the total production from this area is valued at about £6,000,000.

Judging by the value given for the South Australian output I believe that this is a conservative estimate. I am given to understand the average annual labor bill for the orchard, vineyard, and market garden exceeds £10 per acre. This means that you represent industries which are spending over £3,000,000 annually in labor, in addition to the vast amount of indirect employment in the trades which cater to your requirements. The area under orchards is rapidly increasing, and so far as the suitableness of the land for either fruit production or vines is concerned the area under cultivation can be multiplied enormously. In our own State, within 50 miles of Adelaide, we have scores of thousands of acres of land eminently adapted for these purposes, and I believe the same applies to the other States, though not, perhaps, in close proximity to the capital. The chief problem of the future, therefore, is the disposal of our crops.

Local and Oversea Markets.

" It appears to me that our own local markets have not been developed to anything like their fullest extent. In a hot climate like this fruit should be an article of diet of everyday use on the tables of every class of the community —(hear, hear)—yet through inefficient means of distribution its cost during a large proportion of the year is such that it is a luxury for even the middle class of the population, while the poorer classes have to go without it altogether. Why this is so or what is the best means to overcome it is not for me to say, but I feel strongly that the whole of the present production of fruit is not in excess of what should be consumed in Australia. A great deal of attention is being given to the question of the oversea markets, and in their development the outlet for a large quantity of fruit is looked for. The extension of our oversea trade will depend, first, on opening up new markets for our fruit, and, second, on enlarging our present markets by reducing the cost at which we can place it on these markets. In this connection I am pleased to say that the feeling in favor of direct trade with the provinces of England is steadily growing. The General Manager of our Produce Depot and our Trade Commissioner in London have, from practical experience of marketing fruit and other produce in London, been strong advocates for direct shipments to the outports ; and I think the more the question is studied the stronger appear the arguments to get away from Covent Garden market. The opening of the Panama Canal, with the alteration in the American tariff, is expected in many quarters to lead to a development of the fruit export trade from Australia to that country, and I trust that these expectations will be realised, as, if we can get an entrance into the markets of such a wealthy community, it should add to the prosperity of Australia."

After referring to the operations of the Government Produce Depot, Mr. Pascoe proceeded :—" Dealing with the question of local markets, the figures concerning our imports and exports of fruit are of interest and suggest that our growers are not making as much of the local market as they might. I find that for 1912 Australasia shipped £656,000 worth of fruit and fruit products, and that the declared value plus duty of fruit and fruit products imported into the Commonwealth during the same period was £766,000, showing an excess of over £100,000 in favor of imports. It is true that two of the largest items are dates, valued at £66,000, and bananas, £174,000; but, with the cool storage facilities which now exist, it does appear a reflection on our enterprise that we should import £38,000 worth of apples, £33,000 of citrus fruits, and £135,000 worth of preserved fruits, jams, and jellies. I also note that last year the Commonwealth imports of almonds, with duty, amounted in value to over £30,000. This certainly is a crop which we ought to produce up to our requirements. There may be good reasons for such importations, but these figures should afford food for thought.

CO-OPERATION.

" I would commend to the notice of the delegates the figures showing the cost of the Doncaster Co-operative Fruit Store, which were furnished by Mr. Tully at the recent annual meeting of the Victorian Fruitgrowers' Association. Although head of the department which provides the only facilities of cool storage of fruit in Adelaide, I am a strong believer in the fruitgrowers taking this matter up for themselves. In Victoria I notice there has been, of late years, a decided improvement in this direction, but in our own State no action has yet been taken to establish cool stores in the fruit districts. Working on the lines indicated by Mr. Tully, there is no doubt the growers themselves could run a co-operative store much cheaper than any Government department or proprietary company could do. Much could be done in this and other directions by co-operation of growers, and I am pleased that the co-operative spirit appears to be making greater headway among the fruitgrowers than has been the case in former years." (Applause).

BUSINESS OF THE CONFERENCE.

Notes by G. QUINN, Horticultural Instructor.

The tenth annual conference, composed of delegates representing Fruitgrowers' Associations in all of the States of the Commonwealth, but not from New Zealand, met this year by rotation in South Australia. On Tuesday, October 21st, through the courtesy of the Minister of Agriculture and Irrigation, the visiting delegates were met at Murray Bridge by the executive of the South Australian Fruitgrowers' Association and several officers of the Department of Agriculture, including the Director of Irrigation. The Irrigation Department's fine launch *Alexandra* was placed at the service of the party, which consisted of about 40 fruitgrowers, who were conducted over the reclamation works now in progress at the swamps known as Mypolonga, Pompoota, and Wall, which in all comprise about 2,000 acres. The huge machines used in excavating channels and trenches, filling trucks, and mixing concrete excited great interest and raised the enterprise of the Americans for making and the South Australian department for using such machines higher in the estimation of the visitors. The party was conducted over the works by Mr. McIntosh, who lucidly explained the reclamation now in process of completion. Several hundreds of acres of the higher lands behind the Mypolonga swamp are being provided with main concreted channels, 70ft. and 120ft. respectively above the river, and this area will be cut into blocks for fruit-growing, which may be carried on in conjunction with working a certain area of reclaimed swamp land for fodder-raising as well as dry back country for running stock. Returning to Murray Bridge the delegates continued their journey to Adelaide by the evening train.

The sittings of the conference in Adelaide, presided over by the President for the year (Mr. Elliott Hannaford, of South Australia), were opened by the Minister of Agriculture (Hon. T. Pascoe), who, in a carefully-prepared speech of optimistic tone, welcomed the visitors to South Australia.

Preliminary business over, the conference immediately proceeded to demolish various suggestions made by the Federal Fruit Commission, more particularly in respect to its request that two members should be sent to Great Britain to inquire into the marketing of Australian fruits there. The perennial request to raise the duty on lemons and other fresh fruits from countries which are not prepared to give a *quid pro quo* to Australian fruits in their ports was turned down as an act tending to create retaliation most likely by the United States, in whose direction the attention of the Australasian fruitgrower is now being focussed very eagerly, more especially because of the opening the Panama Canal route offers to their produce being placed upon the densely-populated eastern coast of the United States of America.

An outing, *via* Teatree Gully and homeward through the prolific orchards of the Torrens Valley, combined with a social in the evening at a city café completed the first day's proceedings.

When the conference met on Thursday, October 23rd, the freetrade instincts which are natural to the primary producer again asserted themselves, and motions to ask the Federal Government to permit the introduction of bonedust—subject to certain precautions against anthrax coming with it—to abolish the duties on apple-wrapping paper and wire nails were carried with unanimity.

The report of the pomological committee, which met in Melbourne in April last, was presented by its chairman (Mr. L. M. Shoobridge) and elicited a certain amount of discussion. On the whole the work of that committee met with cordial support, and the members were asked to continue and meet again in Hobart next May, if possible. The work of the secretary, Mr. Pescott

(Principal of the School of Horticulture, at Burnley, Victoria), was praised, and the hope expressed that, owing to his peculiar fitness, he would be allowed to continue to act by the Minister of Agriculture of that State. The object of this committee is to secure uniformity of nomenclature for the same varieties of fruits when grown in different States. One delegate very seriously urged the committee to try as far as possible to restrict the lengthy character of some of the names, and the conference in sympathy therein resolved that whenever expedient one word should be made to suffice—truly a sign of the desire of the age to economise in time and energy, and get there in the quickest way, irrespective of the claims of priority of usage, euphony of sound, or depth of meaning expressed in the nomenclature of such of our choisest fruits which have come down to us as the gifts of past generations of gardeners of all nations.

The agenda contained a reference to that "hardy annual" a Federal Bureau of Agriculture. There was evidence that some of the fruitgrowers at any rate are beginning to believe that a properly constituted Federal Department, having for its main objects such scientific investigations as are now being performed in a scrappy manner by State officers, owing to not having sufficient time apart from their other multifarious duties, could possibly justify its existence by doing the work more thoroughly. The motion congratulating the Federal Government on its intention to establish such a bureau was negatived, as was also an amendment suggesting the confinement of such a bureau to scientific research, but in each case the margin of defeat indicated that since previous conferences the prejudices of fruitgrowers towards Federal projects are narrowing down.

A committee brought up a report outlining the grievances of the fruit trade in respect to inter-State traffic. This claimed there should be a uniform gauge of railways, with an adequate supply of louvred and insulated cars, and that the fruit in transit should be put down, not dropped. In regard to steamship transport they considered deck space, far removed from funnels, covered with awnings to allow a passage of fresh air should be available; and, further, laborers when loading cargo should walk on planks, not on the fragile fruit cases, padded against collapse only by the fruit they contained. All boats should have cold storage and dry air systems kept at temperatures, 45° Fahr. for northern and 34° Fahr. for southern fruits, and slats should be used between the layers of cases to permit the maintenance of a more even temperature throughout the hold. The fruit should be handled by trays in lieu of rope slings or nets, and the cases should be stowed on board and removed to the wharf more in keeping with the fragility of their contents. In the expressive words of the report the cases should be placed and not thrown or dropped into their places; and, lastly, the passengers should be prevented from broaching the fruit in transit. Truly a multitude of grievances; some, perhaps, crying out for that which is in store for the fruit dealers of the somewhat distant future only, but others again representing needs for reform which have raised the gorge of everybody who can view these matters in anything like a rational and fair-minded manner. Those who have witnessed the effects of the rough, thoughtless habits of the stevedore, and the immense losses of good fruit through unsuitable stowage provided on the coasting steamers can fully indorse the crying need there is for a little more of the spirit of the golden rule entering into the question of the carriage and handling of such a commonplace article as fruit.

Fruitgrowers are as much interested in " cases " as medical men or lawyers, and if the discussions at this conference represent the opinions of the trade they differ almost as much in what they believe to be finality. Again and again, year after year, this question has been debated at these conferences, and the arguments tend to flow in circles. Those, however, who attempted to introduce new sizes or capacities were crushed by the arguments of a well-known South Australian grower who held up to them the ridicule which confronts those persons who give evidence that they do not know their own minds. Certain sizes of cases were recommended by the conference which sat in Brisbane in 1911, and after being indorsed by the Sydney conference last year, were accepted by the conference of Ministers of Agriculture and embodied into Bills, some of which have already passed into law in certain States. Eventually it was resolved to stand by previous decisions and to recommend that all standard fruit case legislation should provide for new shapes or sizes being fixed by proclamation and not by Act, thus smoothening the way for reform as the needs arose.

Under the heading of " Stowage on Steamers " the question of the " dropping of fruit cases " again received attention, and it was claimed that Australian fruit would be worth at least 1s. per bushel more on arrival in Europe if it were carefully placed and not dropped in position by those " autocrats of the wharf," the lumpers.

The spirit of co-operation is making headway amongst fruitgrowers, as evidenced by the fact announced at this gathering that the growers of Victoria had decided upon a levy of so much per case of exported fruit being paid to send a representative to London to look into the disposal of their produce, and again the Federal Government is to be approached with the hat to bear half the expense on behalf of the rest of the States.

Regarding the question of dealing with nurseries and orchards in relation to diseases, the desirability of compelling all of the former to register was affirmed, but an attempt to compel orchardists to register was, to put it politely, declared to be best left in the hands of the various States. The mover of a motion which sought to exempt the exported produce of any orchardist who might be declared to have a clean plantation from the operations of the Commerce Act argued the matter from a position which does not, to my knowledge, exist in any State. It was carried by the conference in blissful innocence of what it really meant, or how it would be viewed by those who are conversant with the requirements of the Commerce Act in respect to diseases in exported fruits.

Motions were carried without much discussion to widen the operations of the parcel post as a means of distribution of fruit in small lots ; to standardize the by-laws in each State as to the purity of chemical reagents used as insecticides and fungicides; to compel nurserymen to supply trees true to name and worked on blight-proof stocks, and in keeping with this to ascertain the position of the laws in California respecting the control of nurseries ; to congratulate the Federal Government for its intention to exempt rural industries from the Arbitration Act; to ask the statisticians to use the bushel instead of the cental as a measure of capacity in which to express fruit trade statistics ; and to ask the Minister of Customs to amend the regulation concerning the San Jose scale, so that the export of only diseased fruits be prohibited and not all of the products of an orchard in which this scale exists.

Two valuable papers were contributed by Messrs. Sampson and Davey upon " Co-operative Packing " and " The Outlook for the Fruit Industry of Australia " respectively. The former not only advocated district co-operations, but uniform systems of packing, and there is evidence that the course advocated, which practically coincides with the lines recommended by this department for some time past, is gradually gaining acceptation on the part of the fruitgrowers who export their produce. Mr. Davey's paper was full of the possibilities for widening the markets for Australian fruits, which will arise with the opening of the Panama Canal route to the Gulf of Mexico and the Mississippi region of the United States of America, which is so densely populated.

The members of the conference, at the invitation of the South Australian Fruitgrowers' Association, made excursions through the orchard and garden areas of the Mount Lofty Ranges, and, through the courtesy of the Minister of Agriculture, looked over the Government Produce Depot at Port Adelaide and inspected the facilities for shipping produce afforded by the Outer Harbor.

On Saturday, October 25th, the last gathering of the conference consisted of a visit to the Government Experiment Orchard at Blackwood. The various tests and experiments were inspected with much interest, and it was generally agreed that the results eventually must prove of considerable value to the fruit-growing community.

DAIRY FARMING.

FODDERS FOR IRRIGABLE AREAS.

(By P. H. Suter, Government Dairy Expert.)

In irrigation areas possessing a liberal supply of water, good deep organic soil, a useful rotation of crops will be found in the following :—Oats. pasture, pasture, barley, millet, lucerne. This rotation has much to recommend it, seeing that it supplies a most valuable combination of fodders which, when fed in a suitable condition and in conjunction with a little concentrated food, will prove conducive to high milk yields. Again, as most of our soils are not too strong in humus content, the two years pasture, when fed off and turned under preparatory to the green barley crop, gives back to the soil that highly prized content, "humus," without which irrigation farming cannot be successfully maintained.

It is not an uncommon sight to find a continuous crop failing upon areas whereon water has been continuously used to promote growth. Thus, all persons engaged in the use of water for raising crops will do well to give serious thought to the addition of good pastures upon a portion of their irrigable areas.

The mixtures most suitable for two years pastures will be contained in the following :—(1) Rye grass (perennial) and cow-grass clover, prairie grass. (2) Italian rye grass and cow-grass clover, prairie grass; (3) rye grass (perennial), Alsyke clover, cow grass, prairie grass; and for wet land with bad drainage strawberry clover will thrive and do well.

There are many other grasses, such as Timothy, cocksfoot, Kentucky blue grass, which find their place under various conditions of soil and climate; but where irrigation farming is concerned the first-mentioned mixtures will succeed.

For winter feeding of dairy stock, green barley makes an excellent addition to the ration, stimulating the milk-secreting organs and keeping the cows working at high pressure. Barley on irrigable areas should be sown early—during January and February—and this when being fed to cows should have mixed with it some lucerne and oaten hay chaff. A dairy herd receiving sufficient of this mixture will continue to produce abundantly throughout the winter months. In addition to the above, I cannot too strongly recommend dairy farmers who are growing green crops on irrigated areas to sow down a portion with berseem (Egyptian clover). This most excellent fodder for dairy cows was introduced by Professor Perkins, who has during the last two winters fully demonstrated its high value as a fodder for dairy cows. It is a wonderfully heavy yielder under irrigation; several cuttings can be taken off an acre each season; it is relished by the dairy cows and does not taint the milk like freshly-fed lucerne. Cows receiving berseem immediately respond by an increase in their milk production, it having a very healthy effect in stimulating secretion. Cuttings of berseem at Roseworthy have yielded up to and over 10 tons per acre, and similar results have been obtained at a dairy farm near Adelaide.

Maize Growing under Irrigation.

Japanese millet sown during the spring will give a most useful crop for use during the summer months. This can be successfully grazed or hand fed. Cows relish it, and it promotes a very healthy flow of good milk, more especially when the plant has run well into maturity. The growing of this fodder has given excellent results in other countries possessing conditions similar to that obtaining over a wide area of this State; but little attention is given to its growth with us, whether on irrigable or non-irrigable areas. Farmers situated in the latter areas would do well to sow down a portion of their fallow, and with ordinary summer rains should have a good cut of green stuff; but where water can be applied the millet furnishes an amazing crop. The plant is a very hardy grower, and when sown through every hoe of the seed drill yields heavy returns per acre on irrigable lands. Should there be any surplus growth this can always be cut and bound and made into excellent hay which, when chaffed, is much relished by cows as well as horses.

The last crop in the rotation given is lucerne. This plant, where suitable conditions and soil obtain, has always proved a heavy yielder and excellent milk-maker. It also gives good food results on non-irrigable areas, especially where a fair spring and summer rainfall obtains. It is well called the king of fodders on account of its high nutritive value as a food which, when fed to dairy cows, quickly improves their milk flow. It is so well known that more need not be said of it, further than no cowkeeper should be without a small plot of it in almost any district in the colony. Nevertheless, it should not, as too many advise, be made the whole subject of irrigation farming. Whilst admitting its value as a milk-maker when fed in the green state, in my opinion it proves of greater value when used in co-operation with other crops, and the bulk of the lucerne crop reserved as hay. In this form its value is enhanced when used as a winter feed—preferably chaffed and fed in co-operation with oaten chaff and green barley. In the summer time the food ration of the dairy cows can be largely provided for from the pasture, Japanese millet, maize, and sorghums.

Seeing that this rotation can be arranged on our irrigable areas, I would recommend that the bulk of the lucerne be conserved as hay for the winter months, and then fed with oaten or wheaten chaff and green barley it will be unnecessary to run up a bran bill. To those who grow and feed lucerne the better method to adopt is to cut it instead of grazing ; for cattle, grazing will on most soils tend to destroy the plants, and the stand becomes weedy, stunted, and the lifetime shortened. The feeding-off with dairy cows is also not advisable, on account of the fresh green lucerne giving a strong taint to the milk, butter, and cheese ; whilst it may be added that an occasional loss of a cow by hoven or bloat is likely if hungry cows are turned on when the lucerne is wet. Such loss in this way would seriously affect the yearly profits of the dairy. There are conditions where lucerne fields can be successfully grazed, but this is not so upon irrigation areas where good pastures are laid down for this set purpose, viz., the lucerne conserved as hay and fed as above mentioned.

* * *

DISEASES OF FARM ANIMALS.

TREATMENT OF WOUNDS.

By F. M. JONES, L.V.Sc., Assistant Government Veterinary Surgeon.

(*Continued from page* 300.)

OPEN JOINT.

This is a term used to indicate an injury to a joint, and usually accompanied by discharge of synovia, or joint oil. It may or may not be associated with fracture. If unaccompanied by fracture it usually shows little local or constitutional disturbance at first, but at the end of the second to the tenth day much swelling, with heat and pain, is present, the latter being shown by the animal trembling and sweating. The lameness is excessive, the animal being unable to place any weight on the injured limb. The amount of synovia or joint oil lost at first is only negligible, but increases as the inflammation advances. If treatment be delayed the animal usually dies from septic absorption. Joints most commonly affected are those of the foot, often caused by nail pricks ; fetlock, from kicks ; the knees, from falling ; the hock, from kicks ; and elbow and stifle, due to falling or kicks from other animals.

Treatment.—First rest the animal by relieving the weight of the body by means of slings. Carefully remove all dirt and other foreign matter from the wound, not by scarifying or probing, but by carefully irrigating the wound with lukewarm water, to which has been added some ordinary kitchen salt, *i.e.*, one teaspoon to the pint. Do not apply swabs direct to the wound, only press these above the wound in order to release the liquid contained. Irrigate with a solution of corrosive sublimate (1 to 1,000) ; use an enema pump and not swabs. Afterwards pack with a light pad of boracic lint. Feed light laxative food, to which has been added a plentiful supply of Epsom salts.

CHEST WOUNDS.

These injuries are fairly common, varying in degree from simple laceration of a superficial character to that of deep punctured wounds. The former are frequently caused by lacerations from barb wire, &c., whilst the latter are often due to collisions resulting in the penetration of a vehicle shaft into some part of the thorax or chest.

The treatment of the first class of injury is comparatively simple, and consists of carefully examining and removing all dirt or other foreign matter by thorough cleansing with warm water, to which has been added a little table salt, drawing the lips of the wound together and, if necessary, holding in position by means of a suture, afterwards dusting with boracic powder. The treatment of the second class of injury is by no means so simple, and requires skilful treatment. The treatment depends solely on the situation and extent of the puncture and the damage to the adjacent structures. Very little information of a practical character can be suggested here beyond urging the need for cleanliness at the seat of the injury—clipping of the hair around the wound, irrigating with water that has been boiled and allowed to cool, and to which has been added 1oz. salt to the pint. Remove any ragged edges about the wound, and afterwards irrigate with a solution of corrosive sublimate (1 to 1,000) twice daily. Care and attention should also be paid to the general bodily health, and diet should be of a light and laxative character.

The danger attending this class of injury, apart from actual structural damage, is the formation of pus inside and its consequent absorption, which will result in the death of the animal.

WOUNDS OF THE ABDOMEN.

Injuries in this region, apart from merely superficial scratches, are always regarded with apprehension. The great danger of abdominal wounds in animals is the possibility of intestinal protrusion. When one considers the great bulk of intestines which is supported by the abdominal coats the possible results of an injury here is not surprising.

Abdominal wounds may be divided roughly into two classes—shallow punctures and deep punctures. The shallow injuries involve the muscles, but do not penetrate through the whole belly wall. This is often followed by the formation of many abscesses. The pus forms here, and is not able to escape owing to the smallness of the wound, and consequently burrows its way down between the muscles and their covering. This is followed by pain and swelling, and at the same time abscesses may form in various parts which are hard to heal.

Treatment consists in enlarging the original wound after having carefully clipped the hair from the part and washed with an antiseptic. Inject into the part corrosive sublimate, strength 1 to 1,000. Always use an ordinary enema pump syringe for this purpose instead of swabs. Afterwards dress with boric powder. Diet on light laxative foods. To treat the deep punctures we must work with a definite object in view, namely, to prevent the escape of the intestinal loop down through the opening, at the same time we must allow the full escape of the wound discharges. The most practical suggestion is to take an ordinary bed sheet that has been soaked in a weak solution of carbolic and pass this around the animal's body, keeping it in position by sewing. This will act as a support to the weakened walls and at the same time allow of the escape of wound discharges. Constitutional treatment consists in relieving the bowels by enemas ; on no account should purgatives be administered.

WOUNDS OF THE EYELIDS.

This injury is not by any means rare. It consists of the laceration of the upper lid, and is generally caused by the eyelid being torn on a nail projecting from a stable wall or shed. The laceration may not be extensive, but if not treated surgically will result in a permanent blemish. In treating this injury do not by any means remove a part of the hanging lid. Every piece of tissue here must be preserved for the purpose of suturing. First secure the animal by means of a twitch ; in some cases it may be necessary to cast the patient. Then, after carefully bathing the part with a solution of boracic acid, gently bring the edges into apposition, and assure their remaining so by means of two or three stitches ; afterwards dress with boric powder. Tie the animal up short after the operation by means of a double halter, and allow him to stand with his head facing the door. This will ensure him not rubbing his head and so breaking the stitches.

KNEE INJURIES.

Broken knees is a term that suggests a condition familiar to everyone associated with horses. The cause is due to the severe blow received in falling on the hard ground. Sometimes the result is more serious than a mere breaking of the skin. Frequently the bursal or sac surrounding the joint, and containing the synovia or joint oil, is injured to such an extent as to allow the escape of the oil. Again, as is often the case, the animal in falling slides on his knees and tears the lower lip of the wound in such a way as to form a pocket. Into this pocket collects the gravel or dirt upon which the animal may have fallen, and so is furnished material for further complications.

Treatment.—First obtain clean, tepid water, to which has been added boracic acid. Take a swab of cotton wool, immerse in water, and then place it, not on the wound, but above. Press so that the contained liquid will irrigate the wound below. Repeat this operation until all dirt and foreign substance has been removed. Should there be a pocket present take a sharp penknife and carefully slit a small hole in the bottom of the skin ; this will provide drainage for the wound. Afterwards pack up the wound for two days with the following :—Zinc sulp., 1oz. ; lead acetate, ½oz. to pint of water. Subsequently remove the bandage and treat as an open wound, using a dusting powder of boric powder. Care should be taken to tie horse up short and away from anything upon which he might rub the injured limb.

(*To be continued.*)

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

OPERATIONS FOR NOVEMBER.

Incubation.—No further attempt should be made to hatch hens' eggs. Late-hatched chickens are not worth rearing. A few duck eggs may be set; the ducklings will be available for autumn sales. Turkeys' eggs may still be incubated, as the chicks grow well during the warm weather if properly fed.

Green Food.—Attend to the growth of kails, silver beet, &c. Sow maize at intervals; cut when about a foot high. This green food is much relished.

Shade.—Erect shades for the birds. Galvanized iron covered with two coats of King's compo. is everlasting. Sacking coated with the same compo. will last a couple of seasons and is cool.

The Young Stock.—Separate the sexes. Fatten and sell all culls and surplus cockerels. Keep the young stock growing; feed carefully, and give as much succulent green food as possible. Keep a supply of grit (gravel, shell, and charcoal) under cover where the birds can have easy access to it. Look carefully to the water supply. Keep the vessels in absolute shade; scald at intervals and use a disinfectant, such as copper sulphate 1oz. to the gallon of water. Use this to rinse the water vessels.

The Breeding Pens should be broken up. House the male birds in pens by themselves. Go carefully through the stock and cull out any which are not satisfactory.

Eggs for Market.—Gather these twice daily and store in a cool cellar. Wash all soiled eggs before sending them to market. Remember the value of appearance in all produce.

THE 1914-15 EGG-LAYING COMPETITION AND PUBLIC SINGLE TESTING.

The Hon. Minister of Agriculture has approved a further series of tests to begin on April 1st, 1914. There are various new features, and the tests will be organised as follows :—

Section 1.—Open to the world. Any breed ; 10 pullets will constitute each pen. Entry fee, 10s. Prizes—£10, £5, £3, £2, and £1.

Section 2.—Open to those engaged as farmers, pastoralists, fruit and vegetable growers in the State. Any breed ; 10 pullets in a pen. Entry fee, 10s. Prizes—£7, £4, £2, £1, and 10s.

Section 3.—Single testing, light breeds only. Fee, £1 for each entry of six (6) pullets. Prizes—£5, £3, £2, £1, and 10s ; special prize, £2 2s., highest aggregate points. Limited to 30 entries.

Section 4.—Single testing ; general purpose breeds. Limited to entries from the General Purpose Poultry Society and forming part of extended breed test. Fee, £1 for each entry of six (6) pullets. Prizes—£5, £3, £2, £1 and 10s. ; special prize, £2 2s., for highest aggregate points. Limited to 30 entries.

Regluations and entry forms are in course of preparation, and may be had on application to the Poultry Expert on or after November 10th, 1913.

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

HEALTH.

The health of the birds has been good, and their appearance at the present time indicates that their condition is satisfactory.

DEATHS.

Five deaths have been recorded for the month, as follows :—Four from Section 1—one from cystic disease, one from cannibalism, two from natural causes = 4 ; and one from Section 3, caused through cannibalism.

Judging by a statement which recently appeared in a poultry publication, there seems to be some misapprehension about cannibalism. Cannibalism is not due to errors in feeding, but is without doubt a distinct vice which seems to be inherent in certain strains. I have many records of serious outbreaks, even where the birds had unlimited range in scrub country. This year the trouble has been confined to one or two pens, in which the vice seems hereditary.

BROODINESS.

During the month 84 cases of broodiness have been recorded. Section 1 provided 14 White Leghorns and one Minorca ; Section 2, 29 Black Orpingtons, three Buff Orpingtons, 13 Silver Wyandottes, three White Wyandottes, four Langshans, and two Dorkings ; Section 3, six Black Orpingtons, three White Leghorns, and six Langshans = 84.

EGG PRODUCTION.

There is a slight falling off in the production for the month ; this is seasonable. The 900 birds have averaged over 600 eggs a day for the last three months, or 593·5 for August, 648·9 for September, and 622 for October - a daily average for 92 days of approximately 621·5. Highest monthly score—Section 1, 162 ; Section 2, 135 ; Section 3, 162.

VISITORS.

During the month 40 visitors have inspected the station, making a total of 456 since the 1st of April.

WEATHER.

The weather during the month has been cool and moderate, with even temperatures. Rain fell on seven days ; total precipitation of 2·20.

FODDERS.

The following varieties of green fodders, viz., lucerne, barley, oats, rye, kale, silver beet, sorghum, and maize are making good growth, and should prove ample for all requirements.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, October 1st, the following members being present:—Messrs. G. R. Laffer (Chairman), A. M. Dawkins, C. J. Valentine, G. Jeffrey, C. J. Tuckwell, J. Miller, W. G. Auld, Col. Rowell, Professors Lowrie and Perkins, and G. G. Nicholls (Secretary).

Board Membership.

The Secretary stated that in reply to the resolution from the Conference of West Coast Branches of the Agricultural Bureau, to the effect that the Branches should have a voice in the election of the members, the Minister of Agriculture had stated that, as the board was advisory to the Minister, the selection must remain with him.

Timber on Mount Remarkable.

The following communication from the Conservator of Forests was read by the Secretary:—"Reference to the previous correspondence will show that the matter of the destruction of timber on Mount Remarkable has been dealt with in an exhaustive manner, and a special resolution has been passed to that end. There is, in my opinion, no necessity to resume any leases now existing, because should a lessee commit any breach of the conditions under the regulation the lease can be forfeited. This department will, with the approval of the Minister, prosecute all offenders on sufficient evidence being forthcoming regarding the lighting of fires contrary to regulation." It was decided to send a copy of the letter and regulation to the Mount Remarkable Branch.

Sheepdips and Saleyards.

It was announced that the following report on the question of establishing sheepdips at saleyards in the country districts had been received from the Chief Inspector of Stock (Mr. T. H. Williams):—"The Government has no power under the Stock Diseases Act or regulations to compel firms to construct sheepdips at saleyards. It is questionable whether all public saleyards would be desirable localities for dips. Corporation and district authorities might, with good reason, object to have sheepdips within town boundaries. It is a breach of the regulations for owners of tick or lice infested sheep to expose them in a saleyard, and it is doubtful if it would be wise to provide dips where they might prove an inducement to careless owners to bring their sheep in. It would be far more profitable to sellers to bring in clean animals for sale. If there is not a sufficient number of dips in a district owners should club together and construct company dips." At the suggestion of Mr.

Jeffrey it was decided to send a copy of the report to the Strathalbyn Branch, which had moved in the matter, with the indorsement of the Board.

MARKETING WHEAT.

The appended resolution adopted by the recent Farmers' Congress was placed before the Board :—"That this Congress urges the Government to take such steps as may be necessary to make bulk handling the ordinary process of marketing wheat in this State." After discussion the Board determined to forward the resolution to the Minister of Agriculture, with a suggestion that he should bring it under the notice of the Premier, with a view to its discussion at the conference of State Premiers.

CONFERENCE MATTERS.

The Secretary reported that resolutions had come to hand from the Whyte-Yarcowie and Gladstone Branches suggesting that all speakers at the annual Farmers' Congress in Adelaide should speak from the platform, and agenda papers should be distributed earlier than usual, so that the delegates might be armed with the feelings of their Branches in respect to the various subjects. The resolutions were received, and filed for consideration by the committee entrusted with the arrangements for the Congress.

NEW MEMBERS.

The following gentlemen were admitted as members of the Branches shown, viz. :—Frances—W. R. Hill; Mallala—W. Curnow; Port Broughton —A. J. Fletcher, C. W. Rantley, T. Pulford; Inman Valley—J. Millard, J. Mitchell; McNamara Bore—J. D. Robertson, T. Robertson, L. G. Perriam, E. C. Blackett; Moonta—G. Morris, M. McDowall, F. Shaw; Tintinara—W. Taylor; Ironbank—G. Justice, T. Wescombe; Butler—A. S. Bawden; Amyton—T. Corcoran; Mitchell—S. Baker, H. Voumard, R. Merchant, P. Green; Gumeracha—F. Redden; Meningie—W. Williams, H. Fleet; Wepowie—P. Burns, J. Burns, J. McMahon; Roberts and Verran—G. Pellew; Mount Pleasant—B. Giles; Morphett Vale—W. Leare, K. Rainsford; Wirrabara—E. H. Piper; Berri—T. Spinks; Yadnarie—P. Breise, J. Kruger; Lameroo—J. Kakoschkie, A. Townsend; Kanmantoo—H. Downing, A. Stewart; Redhill—H. Larcombe, R. Dick; Mundoora—J. W. Barnes, A. Browne, G. F. Johnson; Claypan Bore—L. McCormick; Bandon—R. Crook, D. Crook, A. Dohse, jun., R. Manning; Port Germein—G. H. Ragless, N. A. Ragless, R. O. Hanna, P. Blessing.

LIFE MEMBERS.

The distinction of Life Membership was conferred upon Messrs. H. A. Giles and F. Thompson in recognition of extended valuable service for the Bureau in connection with the Mount Pleasant Branch.

THE AGRICULTURAL BUREAU.

TWENTY-FIFTH ANNUAL CONGRESS.

(*Continued from page* 390.)

Wednesday, September 10th.

Congress resumed at 9·30 a.m. on Wednesday, September 10th, there being a large attendance of delegates. The Chairman of the Advisory Board of Agriculture (Mr. G. R. Laffer) presided.

THE MANAGEMENT OF FARM HORSES.

Mr. R. E. Lines (Gladstone) read a paper on "The Management of Farm Horses" as follows:—

In the management of horses, stabling is one of the first factors to consider. It is necessary to provide a good, comfortable stable with plenty of yard room. The stable should be closed in on three sides, the open side to face the north-east. It is important that the stable and yard be well drained. The roof may be constructed of iron or straw, according to the farmer's finances. While iron looks better and is safer against fire, a straw roof is cooler in summer and warmer in winter, and is very cheaply constructed. The stable should be provided with a good, roomy manger. When given plenty of room, the horses agree better. I prefer to give them their liberty in preference to cooping them up in small stalls; then, when not feeding, they can go out into the fresh air if they choose. Then, when one comes to harness them in the morning their legs are not puffed up to about the size of two, which happens when they are cooped up in small stalls.

Feeding.

We all know a horse cannot work unless it is well fed. I give long hay in the summer when not working too hard, as I think it keeps the horse in better health; but if working hard they must have chaff and corn of some kind. A little long hay may be then given for the last meal at night. It is best to have different varieties of corn for summer and winter. I prefer bran and crushed oats in the summer, and bran and crushed wheat or barley for the winter. The wheat and barley are very heating; but in the winter a horse requires a certain amount of heat-producing food to keep its blood warm and keep it in condition. A practice too common on farms is to turn horses out in the paddocks where there is very little feed when they are not working, for instance, on Sundays and other off days. At such times they should be fed in the stable, as they require rest and time to build up lost condition. Perhaps there is a little green picking in the paddock which some men say is as good as a dose of medicine. They forget the bad effect it has on the horses' appetites. It will put them right off the feed that has the staying powers, namely, chaff and corn. Eaten out stubble paddocks are also very bad for horses to graze on. They pick after the loose grains of wheat and gather up a lot of dirt which causes a stoppage of the bowels. I have seen many a valuable animal lost in this way.

Water.

Horses should have pure drinking water. Well water is preferable, as it is always clean and usually contains a little salt. If dam water has to be used, see that no drainage from any yards gets into it, as it is from such filth that the dreaded blood worms usually come. If horse owners watch these little points they will find they require very little in the way of drugs, and the horses will be healthy.

Harness.

The harness, especially the collars, should be looked after, and I prefer the collars left in the straw state as long as possible, as they are smoother and more level than when stuffed with the inferior hair of the present day, which, after a while, becomes lumpy and causes the horse to bruise its shoulders when pulling hard. The best of all remedies for chafings and bad shoulders is to keep the horse in first-class condition; if this is done the owner will have no trouble with his horses' shoulders. The driver can often prevent what might be a bad shoulder if he is careful, as soon as he sees the horse start to chafe, to simply alter the draft of the hames one way or the other, or to buckle up the collar a little.

The Discussion.

Mr. J. Malcolm (Kadina) said the writer of the paper had not referred to the necessity of well grooming. He (the speaker) thought it was just as essential that farm horses should be well groomed as it was that buggy horses should be.

Mr. J. Scriven (Morchard) asked whether Mr. Lines had any proof that blood worms came in any way from dams:

Mr. J. P. Pontifex (Paskeville) complimented the writer on his admirable paper, but took exception to the statement that many farmers turned their horses out in paddocks where there was little feed on Sundays and other off days. He had always adopted the plan of turning his horses out, as he believed the exercise they got in the paddock was good for them. Of course that was when there was a good picking in the paddocks.

Mr. R. Johnston (Roberts and Verran) thought farmers were rather prone to neglect grooming their horses properly. They would find if they groomed the horses well before starting work in the morning they would have little trouble as regards sore shoulders.

Mr. W. Rice (Gawler River) said he had visited Roseworthy College when fallowing was in progress, and had noticed that when the horses were brought in the hose was turned on and they were given a good wash down. He asked if that was beneficial.

Mr. J. Burgess (Tarcowie) thought one cause of sore shoulders was that some farmers did not pay sufficient attention to the draught of their implements. If they looked into that matter they would find that it caused more damage to a horse's shoulders and withers than they were aware of.

Mr. H. H. Giles asked if a farmer had 20 or 28 horses would the writer recommend that one yard be used for the lot, or would he have separate yards, as there were all kinds of horses—old, timid, quiet, vicious, &c.

Mr. S. Bottrill (Narrung) did not think it advisable that a number of horses should be fed from one manger, as very often some horses on being put in the stable after working would lie down, and the other animals got all the food.

Mr. W. H. Smith (Naracoorte) said he made it a practice to tie up his horses, always using a strap instead of a rope. Then in case of fire or anything else happening the animals could break the strap and get free. Tying up the horses also ensured each getting its proper share of feed, and resulted in a saving of time. He preferred to feed oats in winter, and not in the summer.

Mr. P. J. Edwards (Pinnaroo) always turned his horses out on Sundays and holidays, and had found it beneficial. His horses ate more on Sunday nights, after being in the paddock, than they did on other nights.

Mr. W. Whibley (Booleroo Centre) said that years ago he used to tie his horses up, but had found that a better plan was when breaking horses in to train them to come when called, or at least to turn round in their stalls. He had also found it advisable to groom the horses in the summer months when feeding them last thing at night. If the sweat was left on all night they would be a little stiff and rough in the coat the next morning.

Mr. J. Monfries (Gumeracha) said a good grooming was to a horse as good as a bath to a man. Regarding sore shoulders, he had had 25 years' experience as a settler, and was of opinion that in regard to sore shoulders a great deal depended on the individual farmer. He believed in tight, well-fitting collars for every horse, and the collars should be kept clean. Some horses, however, it was impossible, owing to their temperament, to keep free from sore shoulders. In such cases the best thing to do was to get rid of them.

Mr. R. D. Nicholls (Nantawarra) thought it wise to have a big yard with posts erected in it, so that the horses could scratch themselves against them. (Laughter.) They should also be provided with a place where they could have a good roll.

A delegate did not favor cleaning horses down, but believed in cleaning their shoulders. When a horse was cleaned down he straight away had a roll, and that showed that he liked plenty of mud on him. Sore shoulders were often caused through the traces not being of the same length.

Mr. E. E. Gill (Spalding) said his practice was to have a stall for each horse. He turned his horses out each day and found they benefited by it. If a horse was tied up he could not lie down in comfort.

Mr. N. M. Roberts (Coorabie) asked whether Mr. Lines favored watering horses before feeding. In his opinion it was very injurious to allow them to have much water after feeding.

Mr. G. Hunter (Watervale) differed from the writer of the paper in regard to the use of straw collars. He had always found lined collars better. It was advisable to wash the horses' shoulders with cold water after removing the collars.

Mr. M. A. Neville (Wilkawatt) said it was impossible to keep a whole team entirely free from sore shoulders all the year round in the mallee districts, and that especially applied when the share plough was used. He had found it beneficial to wash the shoulders with warm water and a little washing soda. Some farmers plastered the shoulders with lard or blacklead, &c., but the dust adhered to the plaster and made matters worse. He used false kip collars and found them of great benefit.

Mr. J. B. Beck (Wynarka) said he had ploughed 100 acres, and hardly one of his horses had a sore shoulder. That was due to washing their shoulders and to the use of spring tugs on the chains for a week or two when a horse showed signs of scalding.

A delegate said the best thing to do in the case of a riding horse having a sore back was to take old blueys and stuff them with hair, leaving a hollow where the sore was, and put them under the saddle. The same principle should apply in the case of sore shoulders.

Mr. W. B. Russell (Loxton) was a strong advocate of good grooming. Lots of cases of sore shoulders were caused more through the collars not being groomed than from the horses not being groomed. Another cause was the chains being of unequal length.

Mr. W. J. Sears (Forster) had found that a good way to prevent sore shoulders was to wash the shoulders, if liable to scald, with salt and warm water.

Mr. A. Jamieson (Yongala) was of the opinion that the most prolific cause of sore shoulders was the fact that the implements were generally underhorsed.

Mr. W. J. Booth believed that a lot of farmers overfed their horses. He believed in quality rather than quantity. He would like to know what was considered a fair quantity of corn to give a horse.

Mr. Lines, in reply, said he had a fairly large stable, and never had horses with sore shoulders. He did not groom his horses, because doing so opened the pores of the skin, and the animals were then liable to catch cold. He, however, believed in grooming the shoulders, though he did not follow that practice to any great extent. He agreed that in many instances implements were underhorsed. He never lined the collars until they needed it, because the hair became lumpy. Veterinary Surgeon Desmond had said that blood worms were caused through filth being washed into the dam from which horses drank. Experience had taught him that it was better to tie up the horses. He advocated allowing one hour for breakfast and a quarter of an hour more for dinner. Horses should be watered before feeding, and the bit should be left in the mouths to prevent them gulping the water down. Observation would show that the horses of a man who kept them in poor condition always had sore shoulders. He would not give more than half a gallon of corn at a feed.

Mr. Place (Government Veterinary Lecturer) congratulated Mr. Lines on his paper, which was essentially a practical one. The ideas were those of a man who could back up what he said by what he had to show. The best situation for the stable was one sheltered from the prevailing winds, whether they were hot or cold. He was inclined to think that it was not advisable to spend a lot of money on them, because as time went on it might be advantageous to change the situation, possibly on account of the accumulation of dung, which provided a home for large numbers of worms and flies, both of which were dangerous to the health of the animals. Where they were obliged to water from dams they should rig up a filter to protect the horses from blood worms. There was no doubt that horses loose in the stalls were able to move around freely and did better than those that were tied up. At Roseworthy the stables were so divided that two or more of the horses could be secured without going into the whole mob. It was not advisable to have more than 16 horses running together. Theoretically, watering should be done before feeding, but so far as the early morning watering was concerned little harm would be done by giving it after the morning meal. Barley was one of the best feeds for bringing a horse up to sale condition, but it was not so good for hard-working condition, for which oats were best. There was no objection to the reasonable feeding of wheat—they could very well give two-thirds of a gallon of old wheat per day per horse. New grain would be found to disagree with the animals. When they were losing condition it would be found that the collars fitted badly, and sore shoulders would very likely result. It was a good idea to provide two collars for each horse when practicable. In any case it was better to pad the collar than to cut it. A piece of thin zinc could be advantageously placed over it. The value of grooming was very considerable, but it was better to leave it alone than to half do it. If the horses had the opportunity of rolling and shaking they would clean themselves. A rotary brush could be fixed on to the hand-clipping machine, and one boy and one man could with this clean eight horses in well under half an hour. He did not hold with hoseing the animals. Every stride the animals took when they were tired took more out of them than three steps when they were fresh; therefore it was not advisable to work them after sundown, and the longer they were given for meals the better.

MANURES IN RELATION TO VINES.

Mr. H. E. Laffer, Lecturer on Viticulture and Fruit Culture, Roseworthy College, read the following paper on "Manures in Relation to Vines":—

The subject I have chosen to put before Congress is one that will have to receive increasing attention in South Australia. Within the last three years the area under vines has increased from 23,000 to over 25,000 acres. At the last vintage 3,974,838galls. of wine were made and 52,208cwts. of currants and 16,575cwts. of raisins were dried. The quantity of wine exported overseas in 1912 was 461,414galls., and the quantity sent to the other States was over 5,000,000galls. The total value of the vineyard production last year was estimated at £544,200, the value per acre of vines of bearing age being £25 9s. 9d. On those figures, I think, I can claim that the grape-growing industry is one well worthy the attention of Congress.

The wisdom of judiciously feeding the vine with a view to obtaining heavier yields of fruit is probably occupying the mind of the Australian vigneron more fully at the present time than it has ever done before. It can safely be said, however, that, so far as Australian viticulture is concerned, manuring is only in the experimental stage. This will, to a large extent, account for the lack of reliable data on the question, and also for the somewhat contradictory nature of some of the results which are obtainable. When it is considered that the average yield for South Australia for the past five years was only 1·75 tons per acre, it will readily be understood that there is ample scope for improvement.

If we look to the older winemaking countries of the world we find, on the one hand, those who regularly resort to manuring of their vines as a part of the ordinary culture based on commercial principles. Of these, we find such as are carrying on the industry in those areas devoted to the production of table fruit, raisins, and currants, or those heavy-bearing varieties used in the production of the inferior types of wine. On the other hand, there are those who do not practise manuring because their ancestors did not do so, and those who do not openly admit the fact owing to an inborn fear that such an admission would adversely affect the sale of their wines. Amongst the latter we find the northern districts of France, where the finest wines of the world are produced. The reason for such an attitude towards the use of manures may be summed up in the fact that their use, momentarily at any rate, increases the fertility of the soil bringing it nearer to that of the rich soils from which the inferior types of wine are made; also, it is contended by some that the use of fertilisers would impair the quality of the wines which command such fabulous prices. This assertion, however, deals with only one aspect of the case, namely, the amount of available plant food in a given soil. It must be remembered that, in the richer types of soil, the percentage of available moisture must harmonise with the increased fertility of the soil, otherwise no increase in the vitality of the vines would be perceptible. The finest wines of the world are grown upon soil which, from an agricultural standpoint, may be considered poor, and with a rainfall varying from 20in. to 25in.

If, then, we enrich the soil in plant food readily available to the vine without increasing the moisture supply, it is unlikely that the quality of the wine will be impaired, except from a sentimental standpoint. The fertility of any given soil must be gauged, not by its percentage of moisture, nor by its supply of available plant food, but by a combination of the two factors. So far as the Australian wine trade is concerned, the question of ancestral sentiment has not to be considered, and the point to be solved is whether manuring will pay or not. It is clearly evident that 100 tons of grapes from 50 acres of vines is a much better paying proposition than a like amount from 75 acres, and this is the point from which the matter must be considered, namely, increased returns from smaller areas.

Manuring to be profitable involves a little more than actual cost of the manures, for it means that greater care and better cultivation must be given to the smaller area in order to secure an increased weight of fruit.

In advocating a system of vineyard manuring, it is not to the fertile soils of the river lands nor to those choice localities devoted to the growth of table fruits that we look for increased returns, but rather to the less favored districts, where the bulk of the wine varieties are grown. Even in the former, however, it is a matter of doubt as to whether the rich soils, with their strong, robust vines, are yielding their maximum of profit to the growers.

MAIN ELEMENTS REQUIRED.

We may sum up the main elements which contribute to the fertility of the soil, and with which manuring is chiefly concerned, as nitrogen, phosphoric acid, potash, lime, and organic matter. The three former are largely consumed by the vine as essential to good growth and fruit production; and the fourth one, lime, as a necessary food, but more particularly as a corrective to the physical nature of the soil. In the greater part of the South Australian vine-growing areas we may say that nitrogen is deficient, potash is fairly plentiful, and phosphoric acid is deficient if heavy yields are to be maintained. Nitrogen is conducive to luxuriant growth, potash to heavy fruit production, and phosphoric acid to the general health and vitality of the vine and, it is said, to quality in wine. The latter element is taken up by the vines in much less quantities than any of the others.

In the bulk of our vineyards organic matter is deficient, and there is no doubt that the raising of the proportion of humus in the soil will materially assist in overcoming other apparent deficiencies. In fact, it may be said that the question of increasing the proportion of organic matter in the general run of the vineyards is of greater importance than the application of either phosphoric acid or potash, and I will therefore deal with this branch of the subject first. Apart from its actual chemical and physical effect as a soil constituent, the moisture-retaining capacity of any soil is in direct ratio to the percentage of organic matter present. Therefore, if some efficient system of manuring can be practised whereby organic matter is added in such a condition that it is readily incorporated with the soil, apart from its action as a source of plant food, it increases the fertility of the soil by maintaining a more even supply of moisture. To this end the use of organic refuse of any description in a decayed state can be recommended, and one of the best known sources of this is stable or farmyard manure.

Green Manuring.

This commodity, however, is available only in limited quantities, and therefore applicable only to small areas. In addition, the general type of stable manure is not in a form which readily decomposes in the soil except with a large amount of moisture. Thus we find that the only practicable means of applying organic matter to large vineyards is by growing special crops within the rows and ploughing them in as green manure. For this purpose, one or other of the leguminous crops may be chosen, that of greatest utility being peas, with vetches as second best. This practice has several points to recommend it—First, the crop is grown generally with a dressing of artificial manure as superphosphate or potash; second, the crop enriches the soil in atmospheric nitrogen through the agency of its nitrogen-gathering bacteria; third, there is a heavy bulk of green matter ploughed into the soil which has the advantage of being heavily charged with moisture. Thus, it can readily be understood that a crop of peas ploughed in under these conditions represents the equivalent of good farmyard manure. As an additional recommendation it is in a form leading to its rapid decay, even in comparatively dry conditions, and hence rapidly becomes available as plant food.

For districts of low rainfall this practice of green manuring should be of great importance in viticulture, and to this end special provision might be made in planting young vineyards to facilitate the passage of a two-horse seed and manure drill between the rows. For established vineyards, where this is not possible, an old drill cut down to suit requirements should prove a profitable investment. The general practice is to sow 2bush. of field peas with 2cwts. of superphosphate to the acre. In heavy soils deficient in lime the use of 2cwts. or 3cwts. of gypsum can be recommended, or else ½cwt. of potassic manure. Generally, the use of gypsum is sufficient, as its action is to free the natural potash salts in such a soil and make them available to the plants. Much depends upon the time of sowing, and, generally speaking, this should be done before the autumn rains set in. This represents a period when there is not a great deal doing in the vineyards, and, in addition, the seed is in the ground ready to germinate as soon as the soil becomes moist enough. As a preparation, thorough scarifying is all that is necessary, owing to the fact that the soil should be in good order from the summer cultivation.

If good conditions prevail the crop should be ready to plough in by the end of July or early in August. It is generally recognised that the best time to plough the crop under is when the peas are in flower; but, if thought advisable, it may be better to anticipate this period to suit special circumstances. Time should be allowed for the green matter to rot before all the rain has gone; but, owing to the succulent nature of the mass, ploughing can be deferred until fairly late in most seasons. One of the first evidences of the beneficial effect to be derived from green manuring is the manner in which the vines retain their leaves, a fact which cannot fail to increase their vitality. For several years past peas have been sown on a portion of the College vineyard in a soil of a light limestone nature and under conditions decidedly unfavorable to vine-growing.

In spite of unsuitable conditions, the manner in which these vines retain their leaves when other portions of the vineyard are bare is a sure evidence of the benefit being derived by them from the organic matter. Although it is difficult to gauge results as to fruit-bearing under such conditions, it can safely be said that the cropping of these vines has improved since green-manuring was started.

One of the most consistent and convincing tests of green-manuring was carried out at Albury, New South Wales, by Mr. L. Frere. In addition, a series of experiments with other manures were carried out for a number of years, but results did not justify their continuation when set beside those of the green manure plots. At the outset, the growth of vines was weak, and yields had fallen as low as 100galls. to the acre. After some years of green-manuring, the growth of the vines became so strong that it was considered advisable to discontinue the experiment for the time being. In the meantime, the yields from these vines had risen from 100galls. to the acre until they reached from 400galls. to 500galls., and in one instance 600galls. per acre was reached.

It may be contended that the practice of green-manuring necessitates a delay in the ploughing under most conditions, but, even so, there will be little difficulty experienced in getting the crop to decay, which after all is the controlling factor.

Then, again, it is always possible to crop only alternate rows each year where large areas are being dealt with, thus rendering it possible to plough half of the vineyard early each year; in fact, this was the practice adopted in the vineyard at Albury, already referred to. So far, the green crop has only been referred to in connection with the increase of organic matter as a physical improvement to the soil, but it has a further action as the source of organic nitrogen. In this respect it has a twofold action, namely, the accumulation of atmospheric nitrogen on the one hand, and the decay and subsequent nitrification of the organic matter on the other. This nitrogen must undergo transformation into one or other of the mineral forms before it can be assimilated by plants.

In dealing with the addition of nitrogen to a vineyard, it must be borne in mind that in addition to the organic form referred to, there are other purely mineral forms of nitrogen, such as sulphate of ammonia and nitrate of soda, which are readily soluble in water and are in a form that can be absorbed by the plants. The effect of these two forms of nitrogen are characteristic and opposite. Organic matter on the one hand tends to the development of an excess of tannic acid in the wine, thereby materially increasing the keeping quality and prolonging the period of maturing. Mineral nitrogen in excess tends towards the opposite extreme, promoting an excess of albuminoids, which are a frequent source of danger to the resulting wine if not properly dealt with. In the well-balanced soil, tannin counteracts the albumen, causing its coagulation and precipitation.

Many vineyards benefit by dressings of purely mineral nitrogen, and for this purpose recourse must be had to either ammonium sulphate or sodium nitrate. In price they are both high and about the same, but the former will give the better equivalent of nitrogen. Owing to their expensive nature, it is possible to apply them in such costly dressings as to render their use unremunerative, owing to the value of the manure applied being in excess of requirements and beyond the value of any ordinary increase in crop. It is here that the need for experimental work is emphasized, because no hard and fast rule can be laid down for any one soil. As a general guide, it may be said that from 1cwt. to 2cwts. of either of these substances may be applied per acre. Its method of application is in the early spring, either by means of a drill or else placed in shallow furrows along the rows of vines. In addition to these forms of mineral nitrogen, there are various other forms of nitrogenous fertilisers to be obtained, such as dried blood and slaughterhouse refuse; also bonedust and bone super., which contain a fair percentage of nitrogen as well as their phosphatic properties. All these substances are valuable as fertilisers if they can be obtained in sufficiently large quantities and there is enough moisture to dissolve the vital elements from their composition.

PHOSPHORIC ACID.

South Australian vineyards, in common with the bulk of our agricultural lands, show a deficiency in this element of plant food. Its application may be said, then, to rank next in importance to nitrogen. So far as manuring is carried out at the present time in South Australian vineyards, superphosphate is, in many cases, the only form of fertiliser used. There can be no doubt, however, that where super. is giving good results at the present time the need of organic or mineral nitrogen will become apparent in the near future if consistent yields are to be obtained.

The vine uses less phosphoric acid in proportion to its growth and fruit production than do most plants, but nevertheless it is of vital importance to the general health and fruit development of the vine. Particularly does this apply at the latter end of the summer, when the plants are ripening off their wood and storing up in the pith a reserve supply of nourishment to feed the young growth in the early spring. The use of super. in connection with green-manuring has been dealt with, but whatever may be the claims of this practice, it must be remembered that in many cases phosphatic manures directly applied are giving excellent results.

There exists a considerable difference of opinion as to the best time to apply phosphates, but if we look into the matter carefully we find that it depends upon the type of soil and the amount of moisture available during the growing season. Being a slowly soluble manure, it is generally recognised that it should be applied in the winter months along with the first ploughing, and this would appear to be the most common practice. There are some growers, however, who prefer to drill in their super. during the summer months, while others, again, claim the best results from spring application. The first case suits the bulk of our vineyard areas. In the second, the result of the manure is not looked for until the following year, and the third is adapted to certain special cases, mainly light sandy lands in districts of good rainfall. The latter is the case on those light-colored sandy soils, such as are found in portions of the Barossa district. Upon these soils winter application of superphosphate gave no increase, as the manure was leached from the open loose soil by the winter rains ; in fact, it is said that one grower applied a heavy dressing of super. to a vineyard upon a slope during the winter, and in the spring found the greater part of it in his dam on a lower part of the property. With spring application on the same class of land yields have been increased fully 100 per cent.

It must be remembered that this class of soil is very poor in its natural state and incapable of producing heavy crops, but if by manuring the yields can be increased from one to two tons per acre, it is putting such lands to a very profitable use. There can be no doubt that the application of phosphates and the results achieved must depend on the type of soil and on the rainfall of any particular locality, and it is also certain that the greatest percentage increase will be observed upon lands of the type referred to.

As the opposite to the loose sandy soils there are the heavier types, containing a large proportion of clay, which retain the super. in spite of heavy winter rainfall, and, finally, there is the other extreme, represented by those areas of scant rainfall where no results are obtained from artificial manures, except under irrigation. If we take an average of the vine-growing districts, it will, in all probability, be found that the winter application gives best results.

In the heavier types of soil one of the main difficulties appears to be the placing of the phosphate deep enough to allow the vine roots readily to come in contact with it, owing to the fact that the phosphoric acid is persistently retained by clay lands in the upper layers of the soil. Thus it is possible to apply heavy dressings of superphosphate without any benefit accruing to the vines.

This question was investigated in connection with the Rothamstead plots, and an analysis showed that in soils which had been manured for 50 years with super., 83 per cent. of the unused residue of phosphoric acid was retained in the upper 9in. of the soil, while in the next 18in. no accumulation of phosphoric acid was noticed. It was further demonstrated that practically the whole of the phosphoric acid applied and not used by the crops could be recovered with a weak solution of citric acid from the top 9in. of the soil.

At the University of California the same question was investigated by Professor Loughridge in connection with the manuring of fruit trees. Soil of a stiff, clayey nature retained ·30 per cent. phosphoric acid in the first 6in., while the next 6in. had only ·05 per cent. Clay retained 1,000lbs. in the surface 3in., loam retained a similar amount in the top 6in., while sand allowed free percolation to the lower strata. The remedy then must be to place the super. as deep down in the plough furrows as it is possible. Probably the simplest plan is to open out a deep furrow in the centre of the rows, and by means of a simple distributing machine place the manure in the bottom. In the more open, gravelly or alluvial soils there is not the same necessity to apply so deeply, and here, no doubt, application with a drill before the second ploughing will give good results. The quantities for application will vary from 2cwts. to 4cwts. per acre.

POTASH.

Whereas we find nitrogen concentrated in the green portions of the vine, potash, on the other hand, is centred in the fruit, and is responsible for heavy cropping. In combination with the natural acidity of the fruit it forms acid potassium tartrate or cream of tartar. Large quantities of this substance are held in solution by the juice of the grapes, and during the processes of fermentation it is precipitated by the formation of alcohol deposits in the storage vessels as crude tartar ; in fact, so great is the quantity, that this commodity forms the base of the commercial supply of cream of tartar. In view of the amount of potash contained, it will readily be understood that a large supply of this subtance in an available form is necessary for prolific cropping.

It is a well-known fact that an analysis of most of the South Australian soils shows a percentage of potash equal to all general requirements of the vine, but it does not necessarily imply that this potash is in a form readily available as plant food. Possibly some corrective treatment may be necessary to bring about a conversion of the element from an insoluble to a soluble form. Particularly does this apply in the case of clay soils deficient in lime, where the potash is retained in the surface as carbonate and cannot penetrate to the roots in the lower layers. This retention of potash salts is an important factor in the fertility of the soil, whereas the corresponding salts of sodium, which are injurious to vegetation, are leached out by the rainfall.

Plants absorb potash more readily as carbonate than as sulph., and consequently deep-rooted ones, such as the vine, cannot obtain an adequate supply for their needs when it is locked up in the surface layers. Under these circumstances some corrective treatment is needed to release the carbonate of potash. This is usually done with gypsum. A double decomposition takes place between the pot. carb. and calcium sulph. Pot. sulph. is formed on the one hand and calcium carbonate on the other. As sulphate, the potash is washed down into the subsoil and comes in contact with the roots; but before it can be used another conversion into the carbonate must take place. First, a decomposition of the sulphate into the sulphide is brought about, and this in combination with water and carbonic acid reverts to the carbonate. In lighter soils, particularly of limestone formation, potash is deficient, and such soils will probably benefit by the application of any of the potassic manures available. Of these the sulphate and muriate are the most desirable forms.

Farmyard and all organic manures are fruitful sources of potash, but even where these are obtainable the necessity of some additional quantity of the element will be needed to balance the effect of the other nutrient elements. It must be borne in mind that an increased fruit production consequent on the use of potassic manures is weakening in its effect, and therefore the other elements of plant food—nitrogen and phosphoric acid—must be raised in sympathy in order to maintain the vigor of the vines.

LIME AND GYPSUM.

The amount of calcium needed by the plant is not excessive, and is generally covered by the natural percentage of lime in the South Australian soils. Even here, however, lime is in many cases needed, more particularly so in the heavy clay lands. Its effect is mainly physical, namely that of flocculating the clay particles, opening the soil to the passage of water, and tending to free other necessary elements of plant food which may be in an unavailable form. Heavy soil is made to work more freely if well limed, and in soils tending to be sour, owing to an excess of decaying vegetation, the alkalinity of the lime acts as a corrective, destroying the weak humic acids and preventing their accumulation. It is also essential to the life of the nitrifying bacteria, the work of which goes on much more rapidly where there is a good amount of lime in the soil.

Gypsum, or calcium sulphate, has much the same effect as ordinary lime, though it is probably not so caustic nor active in its effect. As a manure its value was over estimated, but its indirect action upon the soil fertility, especially as to the freeing of potash salts, renders it a valuable addition to a vineyard soil; thus it is important to the growth of those deep-rooted crops requiring potash, such as peas, &c., and therefore, in soils deficient in lime, it is the practice to use gypsum when growing peas as green manure. For this purpose ground gypsum may be used at the rate of 3cwts. to 5cwts. per acre. As a corrective to heavy clay soil it may be applied at the rate of 10cwts. to 20cwts., although for this purpose it is not so active as ordinary lime

Dealing with manures in general, we find that an acre of vines will absorb annually 50lbs. nitrogen, 45lbs. potash, and 10lbs. phosphoric acid. After all, manuring aims at the maintenance or the increase of the fertility of the soil, and if this is to be accomplished it becomes necessary to add annually these quantities of the various fertilising elements. As a commercial proposition the increase of the average yield of our vineyards should appeal to every grower, and there can be no doubt that if the matter is dealt with on its merits an appreciable improvement in returns will be found to follow the practice. Appended are some few results of experiments which are available

THE DISCUSSION.

Mr. H. S. Taylor (Renmark) asked the value of tick beans for green manuring. At Mildura the more progressive growers were using these. At Renmark gypsum was being added to the soil with very good results, and some of the stiff land that had previously been regarded as valueless had been brought into cultivation. Excellent results had followed the use of a mixture of 2cwts. of super. and 1cwt. of muriate of potash and sulphate of ammonia. Where poultry and pigs had been run on land planted with citrus trees extraordinary results had been secured. Poultry were also useful in getting rid of couch grass. Horse manure was reported to result in a coarseness of the product.

Mr. Laffer had not grown tick beans for turning in. The utility of the crop depended very largely on the district and the conditions under which they were working. He favored peas, as this crop gave a great bulk of green matter. If the tick bean were better suited to the river conditions, however, it was advisable to use them.

Mr. S. O. Smith (Angaston) congratulated the writer of the paper. He had found that there was a danger of souring the soil by ploughing in peas. At Renmark the practice now adopted was to chop them with a disc implement and allow them to dry, then plough them under. There was a certain amount of nitrogen in bonedust and bone super. He wished to know whether the small percentage warranted their paying £6 10s. for these when they could get super. for £4 per ton. There was no danger of super. leaching if it were applied early in the year. Lawes had discovered that practically the only constitutent that leached out of the soil was nitrogen. The early application of superphosphate to the vineyard or garden would be of benefit, because at that stage the soil was more likely to take in the constituents of the manure.

Mr. G. R. Laffer (Advisory Board) mentioned that the Board had circularised all Branches in the fruit-growing districts with a request that information should be supplied where available with respect to the manuring of fruit trees. He believed that a good deal of experimental work was being carried on in a small way, and this would be of considerable value if tabulated. Whilst very good work was being done at the Government orchard at Coromandel Valley, he thought that if they would take in hand an orchard 20 or 30 years of age, and tackle the problems that would arise in connection therewith, considerable good would be done.

Mr. A. Springbett (Lyndoch) asked whether the manures should be put well down in the soil, or on the surface. He had come to the conclusion that the vine had a set of roots near the surface and another going down well into the soil. When the vines were in bearing, and had a good crop of fruit showing, and a long spell of dry weather was experienced, the grapes withered. If a shower of rain fell, however, they would swell out to their proper size. Some of the growers at Angaston ploughed a deep furrow between the rows and the manure was put into this ; others drilled it in.

Mr. C. Morgan (Ironbank) asked whether stable manure was not too dry for use in the Mount Lofty Ranges.

Mr. Laffer said, in regard to the souring of land by ploughing in peas, this would depend largely on the type of soil on which they were working. In districts where the rainfall was not excessive, and on soil which during the summer months tended to become somewhat dry, there was little danger of this. If it did occur it was probably due to the insufficiency of lime. The amount of nitrogen in bonedust and bone super. would be available to the vines in districts where there was sufficient moisture to dissolve it, but generally the more active class of manures, such as super. on the one hand and one or other forms of the mineral nitrate on the other, would prove more profitable than either bonedust or bone super. Winter manuring in some of the very light sandy land showed no appreciable results on the crop, because the phosphoric acid was leached out. The early or late distribution of manure was a matter for experiment. Some favored summer manuring, as the return was not looked for until the following year. Others put it in when the first active growth was going on. This represented a time when there was a great deal of moisture in the soil and little chance of leaching. It was generally recognised that the thorough cultivation of the soil when the vines were being put in was of considerable value. When planting he favored placing a good supply of well-rotted stable manure in the bottoms of the holes, covering it with a layer of soil and putting the vine on top of this. Poultry manure was one of the richest organic manures, and there was no doubt that where it could be applied in conjunction with water it gave excellent results. The use of a complete manure was preferable to the use of a single manurial element. Under ordinary vineyard conditions manure which might be looked upon as the most valuable would not give the same results as they would under irrigation. Poultry running in the vineyard kept the soil loose, killed insects, and added manure to the soil. If they cultivated lightly they got a surface rooting, but with deep cultivating the roots went down deeply. The deeper they got the manure into the heavier soils the better. With the lighter soils it would wash down. Generally stable manure required a considerable amount of moisture to make it available. It acted as a mulch, restricted the effects of capillarity, and the evaporation of the moisture.

EVENING SESSION.

Mr. G. Jeffery, a member of the Advisory Board, presided over a large attendance of delegates and visitors.

WATER SUPPLIES.

Mr. L. Keith Ward, B.A., B.E. (Government Geologist), gave an address on "Water Supplies, with Special Reference to Underground Water."

Mr. Ward, whose remarks were illustrated by a number of fine lantern slides, said that a great deal of what he intended putting before the Congress was due to the researches of his assistant, Mr. Jack, who almost from the first day of his appointment had been engaged in inquiring into the question of the underground water supplies of South Australia. The publication of Mr. Jack's work on Eyre's Peninsula had led the Minister of Agriculture (Hon. T. Pascoe) to suggest that he (the speaker) should deliver an address on the subject before the Agricultural Bureau Congress. The matter had gone on to the Commissioner of Public Works (Sir Richard Butler), with the result that the delivery of the address had been arranged. He wanted first to give those present some idea of the work done by the Geological Department in the direction of assisting in the discovery of water—work which was done mainly for the benefit of the agriculturist. Afterwards he would say something in regard to the divining rod and its efficacy or non-efficacy.

RAINFALL.

The question of water supply was of course a very large one, many phases of which could only be briefly mentioned that night. Of the figures relating to the progress made during the past 25 years which had been placed before Congress during its sittings, he thought those which gave the rainfall over the agricultural areas were the most interesting. Those figures showed that the rainfall had dropped from 25in. in 1889 to a little over 14in. during last year. He took it that that decrease was not due to a decrease in the rainfall average, but was due to agricultural development having proceeded into the less watered parts.

Rainfall was the ultimate source of all useful supplies of water. There were seven artesian basins in the State, and in regard to the supply of water to those basins the first thing, of course, was the rainfall. Some people had tried to claim that a certain amount of water was provided to those artesian basins from the innermost parts of the earth ; but that was not the case, and it was the rainfall only, or practically the rainfall only, which supplied water to those basins. Hot springs near volcanic centres might be the outlets by which the deep-seated water of the earth's mass reached the surface, but those were not to be considered of any economic importance in that connection. In South Australia our water supplies were all concerned with rainfall, though in some cases (some of those artesian basins) supplies depended on rain that had fallen outside the limits of the State. In all other cases the rainfall over a district was directly related to the underground water supply of that district. They were very frequently asked why in some parts of the State they did not get the same underground supplies as in others. The first reason was that they did not have the same rainfall. The greatest rainfall in the State was in the Mount Lofty Ranges and the extreme South-East. The rainfall in the Mount Lofty Ranges was nearly 47in. per annum. Mr. Bromley (the Meteorological Officer for South Australia) had shown that the rainfall of the State was due to three important causes, viz., (1) proximity of the Southern Ocean, (2) the westerly winds which reached the south coast in the winter season, and (3) the mountain ranges which pushed the line of 10in. rainfall from Port Augusta to beyond Blinman. Mr. Bromley had also shown that in the settled areas of the State from 70 per cent. to 90 per cent. of the annual rainfall fell during the growing period—from April to October. One of the most useful things a farmer could do was to keep his own rain chart, and to keep it by months. It was most important to know exactly what was the distribution of the total annual rainfall for each district separately.

WHAT HAPPENS TO RAINFALL ?

The total annual rainfall, *i.e.*, the amount of water caught during a year in a rain gauge, was not the only thing that had to be taken into consideration, although it was the factor of greatest importance in matters concerning water supply. The destination of the water that fell as rain, or in other words, what happened to that rainfall, had to be considered. There were three things which might happen to rain. It might run off in a stream; but in South Australia there were exceedingly few running streams, and the run-off in that direction was practically negligible. Where, however, the rain did run off in streams it resulted in the ultimate return of the water to the ocean, or its accumulation in basins of internal drainage. Then part of the rain was evaporated, either directly or indirectly. Some of the rain was evaporated at once by hot, drying winds, and the many salt lakes in the interior were an evidence of the high amount of evaporation in the inland districts of the State. The third thing that might happen to the rain was that it might percolate into the ground. Percolation might be either visible or invisible. The percolation was obvious in the case of a light rainfall upon open-textured soils, so that there was no run-off.

UNDERGROUND WATER.

It was that part of the rain which sank into the ground with which our underground supplies were wholly concerned. There was a great deal of percolation which could not be seen, but which could be measured. If a stream running over porous soil was measured before it passed over that soil, and then after it had done so, there would be found a great diminution in its bulk of water. On the other hand a clay soil would not allow of percolation. Those present knew that clay was one of the best things with which to make a tight bottom for a dam, and that very tightness prevented the water from percolating. He had been asked to recommend the sinking of bores on hilltops covered with clay, but how could the water get down through dense clay ?

The water which found its way underground found storage in rock pores or crevices rather than in actual cavities, which only occurred in limestone country, such, for example, as was to be found in the South-East, where the limestone caverns might be seen at Mount Gambier in the walls of the great sinkhole in the centre of the town. In the great majority of cases, when they were dealing with underground water they were not dealing with open channels at all. The usual storage reservoirs were beds of sand or gravel, with little cementing material. In most of the artesian basins of South Australia the water-bearing layer was nearly loose sand. When the spaces between the sand grains became entirely filled up with mineral matter, a bed rock, which was impervious, was formed. In the case of any water that might occur in compact rocks (where mineral matter existed between the grains) they could only find the water stored in cracks or crevices. This was the case in the Mount Lofty Ranges, which were composed of slate. The quantity of water in the rocks depended on the number of cracks which existed to give storage room for it. This would be filled with water falling as rain up to the ground water table. Ground water was under no pressure. It was only in exceptional cases that a large supply of water was secured in the case of bores put down in such rocks. If there were a storage capacity provided by a fissured zone the supply might be reliable, but such cases were infrequent.

ARTESIAN WATER.

Artesian water was restricted to special areas in which several factors needed to exist together in order that useful supplies might be obtained. These conditions were—(*a*) adequate rainfall, (*b*) relatively porous rocks, so disposed as to admit the water and allow its passage ; (*c*) relatively impervious rocks, so disposed as to confine the water in the more porous beds ; (*d*) the tilting of the porous beds ; (*e*) the absence of any easy escape for water at lower levels than the ground surface at the site of the well or bore.

The common type of artesian basin was that known as the "one-sided," an example of this was the Adelaide Plains Basin. There was a tilting towards the sea which cause the water at the lower end of the slope to rise close to or to the surface. The Willochra Valley constituted what was known as a "valley basin." The supply depended on the place where the intake was, and upon the quantity of the water that passed underground by percolation. The reason they had a good supply there was that a quick run off was provided by Mount Brown and Mount Remarkable, and it reached the porous beds in a state of purity and was sucked up for utilisation at Bruce or Hammond.

SOUTH AUSTRALIAN ARTESIAN BASINS.

The artesian basins of South Australia were—(1) The Great Australian Basin, with a total area of 550,000 sq. miles, of which 112,000 sq. miles were in South Australia. The intake of this basin was principally in Eastern Australia, where the rainfall was good. The general movement of the water was towards west and south-west, except to the Gulf of Carpentaria. This basin was mostly artesian. The quality of the water was good, but in Queensland it was better than in New South Wales, and in the latter State it was better than in South Australia. (2) The Murray River Basin, of a total area of 106,000 sq. miles, of which about 27,000 sq. miles were in South Australia. The intake for the best waters of this basin was in county Lowan, Victoria, where there were 2,000,000 acres with a rainfall of 25in. and no run-off. The northern and western portions of the Murray River Basin were salt, and possibly the supplies from those portions came from a different source. It was mostly sub-artesian, except near Tintinara. (3) The Eucla Basin, with a total area of 76,000 sq. miles, of which 21,500 sq. miles were in South Australia. There was one flowing bore in Western Australia from this basin. The water was fit only for stock, but possibly the supply might be utilised in connection with the Transcontinental Railway. (4) The Adelaide Plains Basin, of about 1,000 sq. miles. The intake of this basin, to which he would refer later on, was along the foot of the Mount Lofty Ranges. (5) The Willochra Valley Basin, which was small but useful, and of which little was known in detail. (6) The Port Pirie Basin, which was salt in patches and, like the Adelaide Plains Basin, was artesian in places. (7) The Cowell Basin, which was sub-artesian, the main body of the water being salt.

The future of the underground waters of the eastern part of the continent was of very considerable importance. In Queensland, where the bores were put down in great numbers, several had ceased to flow, and it was necessary to pump supplies. They would perhaps have to wait for generations before the supplies were made up again. Victoria had put down a great number of bores in the Murray Basin, especially to the east of Pinnaroo and Bordertown. The source of the greater portion of the water was situated east of Naracoorte. The rainfall there was nearly 25in. in places, and it all went underground. Care should be taken not to drain this supply provided by Nature. The supplies in this basin were generally sub-artesian. At Tintinara one Government bore was just artesian, and there were a number south of this place where flowing supplies were obtained. Flowing bores were also to be seen on the Adelaide plains, viz., those situated at Paradise, Morphettville, Dry Creek, &c.

The exact depths at which water would be found at various points could not be definitely stated, but there was a well-defined basin passing along the coast and occupying about 1,000 sq. miles. The quality of the water was on the whole excellent, and only deteriorated in the vicinity of Port Wakefield.

In connection with the Cowell Basin a salt creek died out on the intake, with the result that the water was vitiated. But there were points at which it was possible to make use of the water, *i.e.*, where the fresh water rapidly flowed down the hills and was lost in the upper portions of the intake beds. The salt content in water taken from the ocean by the winds was distinctly measurable. The evaporation was exceedingly high, and the result was that salt was continuously being added to the soil. One other question which arose in regard to the Cowell Basin was why the same supply of water was not got on the western side of Spencer's Gulf as was obtainable, say, at Port Pirie? The answer was that Spencer's Gulf had been caused by a great fracture in the earth's crust, with the result that the geological features on the western side of Spencer's Gulf were quite different to those on the eastern side.

SALT CONTENT OF RAIN.

Another question of importance was the salt content of rain. The winds which swept up the moisture from the sea and sent it down on the land as rain also took up salt, and actual experiments in New Zealand had proved that every inch of rain that fell over an acre of ground distributed 4¾lbs. of salt.

The evaporation of the water meant, of course, the concentration of the salt in the water that remained. This question was of high importance in South Australia on account of the general lack of surface streams to convey back to the sea the salt introduced in the rain. Our great salt lakes were the ultimate repositories of much of the salt.

GROUND WATER.

Ground water was water which was not under pressure. Water lost below the surface by percolation sank down and saturated the permeable portion of the earth's crust which lies below the ground water level, or ground water table. This table was apparent when a well was sunk, for it was marked by the surface of the water. The position of the ground water level depended on (1) the porosity of the beds, (2) the annual rainfall and variations thereof with seasonal changes, and (3) topographic relief. The ground water table was much less irregular in any district than the surface beneath which it lies. That was to say, the ground water table was very much nearer the surface in a gully than on the top of a hill. It was important to remember that the ground water was always in motion, however slow that motion might be. The direction of the movement was usually the same as that of the surface drainage, for the reason that the ground water table conforms in a general way with the broader surface features. The movement of the ground water was thus down grade towards the lowest point of a district. He laid special emphasis on that point, because he had seen most extraordinary sites chosen for wells. In choosing a site for a well, especially in hilly country, the first thing to do was to get down into a gully. It was very important to get down as low as possible. It had to be remembered, however, that the general drainage features of every area must be considered carefully, and a well site must not be chosen at a point where other indications point to the probable existence of salt water. That was to say, low level sites must be avoided where underground circulation was very slow or absent.

TYPES OF WELLS.

The various types of wells were :—

(1) Wells in porous rocks in districts where rainfall is abundant, *e.g.*, between Naracoorte and Mount Gambier.

(2) Wells in areas characterised by very massive travertine limestone at the surface and by sheaoak vegetation, *e.g.*, Wurkagie-Witera, Polda, Terre, Oakdale (counties of Robinson and Musgrave).

(3) Wells in alluvial deposits—" soaks "—
  (*a*) Soaks at the foot of bare rocky slopes ;
  (*b*) Shallow soaks in creeks ;
  (*c*) Deep wells in main valleys.

(4) Wells in fissured rocks in the hills where there is a good rainfall, *e.g.*, in the Mount Lofty Ranges.
(5) Wells in porous strata bottoming on impervious rocks above the level of the main ground water table, *e.g.*, Condodringie (county of Robinson).
(6) Wells sunk to suspended water-tables, *e.g.*, Challner (county of Robinson).
(7) Wells obtaining fresh water from a top layer resting directly upon salt water, *e.g.*, Cameron's Courela (county of Robinson).
(8) Wells in sandhills—
  (*a*) Coastal wells in which the fresh water lies upon clay or upon salt water;
  (*b*) Inland wells in which the fresh water rests upon some impervious material.

FACTORS DETERMINING QUALITY AND QUANTITY OF WATER.

The factors which determined the quality of water obtained by wells sunk to tap the ground water were—(1) The amount and distribution of the rainfall; (2) the character of the rocks in which the water occurred and the soluble contents of those rocks; (3) the character of the soil on which the rain falls and its absorbent power; (4) the distribution of vegetation; and (5) freedom of contamination by sewage or by admixture with inferior water. The quantity of water obtained depended on—(1) The type of well; (2) the porosity of the water-bearing beds; and (3) the rate of supply of water to those beds. Ground water lay above artesian water in some parts of the State, and was separated from it by clay beds. If the clay seam was only a few feet below the surface the water was indirectly evaporated, but if the clay bed was a little deeper they had a good storage basin. Most of the creeks in the Gawler Ranges and Flinders Ranges were filled with gravel wash, and that was the place in which to sink a well. As regards the Gawler Ranges, the water was gradually flowing to the sea. There could be no question but that the underground water supplies would improve as clearing of the land went on.

CHOICE OF A SITE FOR A WELL.

What were the things which should guide them in choosing a site for a well? If they were seeking a supply from an artesian or sub-artesian basin, the matter was a very simple one. In the case of an artesian basin they must not get too high if they wanted a flowing supply, for the reason that they might get above the hydraulic grade. In the case of a sub-artesian basin the usual custom was to choose a site on a rise, whence the water might be distributed by gravitation. With regard to the choice of a site in the hills: In fissured rocks they should always choose gully sites, so that they might secure supplies from the convergent underground flows from both sides of the gully. It was impossible to hope for supplies if the surface was covered with impervious clay, such, for instance, as was to be found near Blackwood.

In regions such as Eyre's Peninsula it had been found that all useful supplies of water depended upon the existence of the following conditions:—(*a*) A gathering ground from which the rain water ran quickly to a place where conditions favored rapid percolation to a depth sufficient to prevent direct evaporation or the return of the moisture to the atmosphere by capillary action, and through the agency of the vegetation; or (*b*) a soil, such as sand, so readily absorbent as to enable the water to sink quickly to a depth below the influence of dissipating agencies and to come to rest upon an impervious layer, or upon the surface of the main body of ground water.

Timbering of Wells.

For the timbering of wells jarrah was the best, ti-tree came next, and then native pine, though the latter wood was distinctly inferior to the other two. Square wells of small sections were calculated to prevent the collapse of wall plates. Large wells were of no advantage where a windmill was used. It would be found of advantage to sink a well as small as was convenient, and if provision for storage was needed, this could be made by chambering out the lower sets near the water level.

Benefit of Clearing.

The clearing of native vegetation, such as the mallee, would be found to add materially to the available underground supply of water. The removal of absorbent surface soil, if it was underlaid by rock or clay which would give a better run-off, would improve the catchment. In Western Australia it was recognised that a couple of years after ringbarking soaks appeared.

Useful Waters.

Experience in South Australia had shown that the amount of dissolved salts in water that could be regarded as useful was greater than was generally believed to be tolerable. Animals that would unerringly select sources of drinking supply that were lowest in dissolved solids, and avoid those which were highest, would, if placed in regions possessing supplies of poorer quality, accustom themselves to a mineral content far greater than that in the poorer waters which they would not previously touch. This adaptability was in no country more remarkably shown than in Australia. The best waters contained less than 20 grains per gallon, whilst those containing 100 grains to the gallon were regarded as rather "mineral."

The ascertained limits of salt contents in useful water were as follows:—For domestic or potable water, up to ⅛oz. per gallon, although that containing up to 1oz. to the gallon had been used by settlers for considerable periods in times of necessity. Horses would work and keep their condition on water containing up to 1oz. per gallon. These animals would live on water containing up to 1¼ozs. per gallon. Cattle would live on that containing up to 1½ozs. and sheep 2½ozs. The presence of bitterness due to salts of magnesium would cause some reduction in the amount of total solids permissible. The methods of testing water for salinity were (*a*) with a salinometer, (*b*) by means of evaporating a measured gallon. It was inadvisable for the amateur to attempt the latter method.

TANKS.

The lecturer described in detail various methods of constructing tanks in different classes of soils. He mentioned that the water caught on iron roofs was equal to about ½gall. per inch of rain per square foot. Throughout South Australia the consumption was greatest during the summer, when the supplies from the rainfall were least. It was desirable that the tanks should have a capacity equal to 50 per cent. of the annual rainfall on the roof. The minimum storage should be sufficient to hold 30 per cent. of this rainfall. Care should be paid to the necessity for preventing concentration by evaporation, this being especially important in the case of waters containing appreciable amounts of dissolved solids. Where a new homestead was being planned it was advisable to select the well site first, and arrange the disposition of the outhouses and stables to prevent contamination of the supply. This applied equally to dams and tanks storing surface supplies.

In conclusion, the need for careful conservation of all supplies was pointed out. The reservoirs of ground water and artesian basins were alike far from being inexhaustible. The local sources, he said, would always be of greatest value.

THE DIVINING ROD.

He now wished to say a few words in regard to the divining rod as a means of locating underground supplies of water. The use of the divining rod dated back to the earliest historical times. In the early days it was used (1) to prove the site of old landmarks ; (2) to detect crime ; (3) to guide a traveller on a right course ; and (4) to indicate the presence of mineral lodes. While he would not personally place any faith at all in the claims of the dowser, he freely admitted that many people were honestly convinced that some ill-defined but special power was possessed by the diviner, and he also admitted that there were diviners who were honestly convinced of their own special gift. The geologist, to whom appeal was so frequently made after fruitless expenditure at sites recommended by diviners, might, perhaps, be pardoned for some measure of unbelief in the claims of dowsers. While successes undoubtedly did occur, there were many failures. The general public heard of all the successes, and the geologists heard of some of the failures.

The phenomena of water divining was variously ascribed to (*a*) magnetic or electric influences ; (*b*) changes of temperature and moisture on nervous organisations ; (*c*) radio-active emanations. But all such influences, if they existed, could be recognised and measured by delicate scientific apparatus in quantitative terms. It was important to remember that if the success of the water diviner was based on experience, local knowledge, and geological reasoning, the diviner, although useful to the public, was, so far as divining was concerned, a fraud.

It was a matter of common knowledge to geologists that the successes of diviners were most frequent in regions where few failures could possibly occur. There was abundant evidence of success, but what was that evidence worth when it was fully investigated ? Those successes occurred at sites selected by diviners in an area where water was universal, such, for instance, as on the north-west coast of Tasmania or the Adelaide Plains. He had even heard of a water diviner claiming payment for locating water in the Murray River artesian basin and also in the Adelaide Plains basin. Would a farmer think it remarkable that a man should discover an ear of wheat in a standing crop which would average no more than 9bush. to the acre ? And yet that amounted to the same as locating water in an artesian basin.

A possible explanation of the movement of the divining rod was that it was held in a restricted position which might cause, and probably did cause, unconscious muscular contraction, with the result of the deflection of the rod. It had been found by experiment that unconscious muscular movements happened most frequently at places where the operator's experience had led him to believe that water might be found. Diviners had failed conspicuously in limestone regions where water did flow in well-defined channels.

CONCLUSION.

While it was possible that the diviner might succeed where the geologist failed from unforeseen causes, it was nevertheless true that in the present state of our knowledge the advice of a geologist was preferable to that of a diviner.

It had been his object in his address to show that certain ascertained laws might be formulated from the known occurrences of underground supplies of water, and that all the wells of which they had knowledge in this State could be adequately understood by the proper application of recognised principles. The sections shown on the screen had been drawn with a view to giving those present an opportunity of forming a mental picture of the relation of geological structure to the occurrence of water, in the confident belief that, if the facts had been accurately classified, and if their correlation and sequence had been properly observed and recorded, the statements he had made would appear convincing. In other words, the endeavor had been made to show that all known occurrences of underground water could be explained by natural science without appeal to the supernatural. Human instinct was to appeal to the supernatural when phenomena that were not understood presented themselves. He hoped he had made it clear that the occurrences of underground water could be understood.

Before finally concluding, he desired to refer briefly to what had been termed pseudo-scientific water divining, which was based upon the deflection of a magnetic needle. It was perfectly useless, without a very detailed examination and study of the geological features in the area tested, to take the declination of a needle as a sign of water. A considerable amount of work had now been done in investigating the relation of geology to terrestrial magnetism, and it was admitted that the subject was exceedingly complicated. No detailed study had yet been undertaken in South Australia, and until such work was done no steadfast faith in the operation of an instrument said to detect water by means of the observation of magnetic declination could be justified. (Applause.)

An Interesting Question.

Mr. P. J. Edwards (Pinnaroo) expressed his appreciation of the fine address. He wondered whether the extensive drainage operations which were going on in the South-East would eventually affect the sub-artesian supplies in the Pinnaroo district.

Mr. Ward said that being drained away was ground water. The deeper system which supplied the artesian water would not be touched.

At the instance of Mr. Edwards (Pinnaroo), seconded by Mr. Koch (Lameroo), a hearty vote of thanks was accorded the speaker.

Thursday, September 11th.

Mr. G. R. Laffer (Chairman of the Advisory Board) presided over a large attendance.

BUREAU WORK.

In an address on "The Present Position and Prospective Work of the Agricultural Bureau," the Secretary to the Advisory Board (Mr. G. G. Nicholls) said the present position of the Bureau was strong numerically, and he wished to show that, in addition to a larger number of branches and members, there was an increased interest manifest in the organisation, as was evidenced by the number of members per Branch. In 1906 there was an average of 16 members in each Branch, in 1910 20 members, 1911 21 members, and in 1912 an average of 22 was reached. This was very satisfactory. The quality of the reports was improving steadily year by year. The standard reached was very high, and it was quite a difficult matter to know just how to reduce some of the lengthy papers, because they were so good. During the past year the following important subjects had been dealt with in papers, etc :—Fruit and vegetable cultivation, 57 ; wheat and general cultivation, 156 ; dairying and stock, 32 ; harvesters and harvesting machinery, 22 ;

horses, breeding, feeding, &c., 50; sheep on the farm, 46; hay and haymaking, 28; poultry, 22; pigs, 10; rabbit destruction, 14; fodders and grasses, 26; fencing, 10; afforestation, 10; in addition to a large number of other subjects with two or three papers on each. The Julia Branch had inaugurated a field trial, and this had been carried to a very successful issue. He desired to pay a tribute to the excellent work which had been accomplished by the hon. secretaries to the various Branches. The Bureau was greatly indebted to these men.

PRACTICAL WORK.

In 1896, in the long-settled northern districts the proportion of land fallowed to that under cultivation was 25·9 per cent. In 1911 the proportion of fallow had risen to 60 per cent. The Agricultural Bureau had had a great deal to do with this. The greatest memorial they could raise to the founders of this noble institution was the building up of the Bureau and the making effective of its work in future years. They should forget that they were members of Branches, and regard the Bureau as an institution—a concrete whole. The strength of the British Empire was largely due to the effectiveness of the units composing it, but much was due to the strong spirit of patriotism. The same applied to the Bureau. The possibilities of this institution were almost unbounded. They were now entering upon the second quarter of a century of its existence, and he was hopeful that a distinct forward movement would be made. There was a field of work at present hardly touched upon. He referred to the need for experiment. When systematically carried out these had a double value. In the first place they provided the only means of determining many of the practices that should prevail on many of the farms. Beyond that, however, was the greater benefit, that the experiments convinced the farmers as to the value or otherwise of a given practice. There were only about six Branches which conducted any experimental work, *i.e.*, which had done work which they deemed sufficiently important to report. There was, however, much experimental work done by individual members; but the fullest benefit of this was never realised, because it was never tabulated and recorded or brought under the notice of the farming community in general. There was scope for experimental work amongst fruitgrowers. They knew the questions which could with advantage be investigated. He would only mention manuring, systems of pruning, and cultivation under varying conditions. Irrigationists on the Murray swamps were practically unanimous that as a body they knew very little about working the swamps, and there was a tremendous field for experimental work there. Among the wheatgrowers he would only refer to the question of manures. In the case of one or two Branches experiments had shown that a few extra pounds of super. per acre above the amount generally put on in the district gave an enhanced return of several bushels to the acre. Professor Lowrie and Professor Perkins were continually telling the farmers that they were not putting sufficient super. on to the ground, that there was not enough to encourage a strong growth of feed in the stubbles, and that in many districts there was not as much phosphoric acid put on as was taken out by a good crop under normal conditions. If they did a little experimental work in the Branches they would be able to come prepared either to admit the truth of these assertions or to disprove them. The work that had been done in this direction by individual members was in many cases somewhat haphazard. No man could with certainty distinguish a difference of 1bush. per acre in a standing crop. If 1bush. per acre more could be won from the land it would mean thousands of pounds into the pockets of the farmers. The question was whether the Bureau should undertake any systematic experimental work, and if so, how it could be done. It would be an insult to farmers to suggest that there were only half a dozen men in the State who were capable of carrying out experiments successfully. There were some in almost every Branch of the Bureau. It was necessary that the Bureau should decide whether this was advisable, and then to proceed to arrange matters. If the results of the work were to be accepted without question there must be a small committee in each Branch to supervise, termed the "local experimental committee." This body should decide what experiments should be conducted. They should measure the plots on which the experiments were conducted, and satisfy themselves that the soil was fairly uniform in character. They should check weights of produce, &c., and all calculations made. One of the committeemen should be the keeper of the records. If they expected one man to do all the work they would have difficulty in getting volunteers. This would make a very attractive feature for the homestead meeting or visiting day. If the results were sent in to the Department to be published in the *Journal*, and afterwards to be summarised in the Annual Report of the Bureau, he ventured to say they would secure valuable data in this connection such as had not been previously collected in this State. To carry this into effect it might be wise to appoint a committee from such a meeting as this, consisting of representatives from the various districts. Failing this, the individual Branches could take the matter up, appoint a small committee, and go into the details.

Mr. W. H. Smith (Naracoorte) complimented the Secretary on his address. The position in regard to experiment was, however, that the busy time on the farm was just that when the experiments needed most attention. The farmer took more interest in and paid more attention to work on the Government farms. One way out of the difficulty was a higher scientific education in regard to agriculture. They had conducted experiments to determine the most suitable quantities of super. to use, the quantity of wheat to sow, and they had come to certain conclusions. He thought that if the Government would send the officers to meet the farmers and give practical demonstrations and advice, more good would be done.

Mr. A. Beviss (Strathalbyn) thought the suggestions of the Secretary in this regard should be carried out.

Mr. C. Ricks (Cherry Gardens), who went in for fruit and vegetable growing, gave an instance of the value of experiment on the farm. Fifteen or sixteen years ago he was told that oranges would not grow in Cherry Gardens. He put in trees, however, and at present had three acres of oranges which were doing very well.

Mr. F. Masters (Roberts and Verran) favored the idea of the Branches conducting experiments, because they were more acquainted with the local conditions. He moved, "That this Congress recommends that more experimental work should be conducted by the Branches." This resolution could, if carried, be passed on to the Branches.

Mr. R. Johnston (Roberts and Verran) seconded the motion.

Mr. D. Carmen (Pine Forest) supported the motion. He was quite satisfied that there was a great deal for agriculturists to learn, and the farmers were in a position to conduct experiments to the advantage of the farming community.

Mr. S. Giles (Mount Remarkable) said the Government was doing valuable work in this connection ; but the value of the experiments was not brought home unless they were verified by the farmers themselves. The Government lead the way, and the agriculturists should adopt their advice to meet their individual requirements.

The motion, "That this Congress recommends that more experimental work should be done by Branches," was put to the vote and carried unanimously.

Mr. J. R. Coles (Longwood) moved "That the Branches be divided into groups, and that each group be advised to conduct experimental work along certain recommended lines simultaneously, and that the Branches constituting the several groups should communicate direct with one another in connection with the work." By this means, he thought, a great deal of useful information would be disseminated.

Mr. C. Ricks (Cherry Gardens) seconded.

Mr. G. G. Nicholls moved "That a committee be appointed from those present, to consist of two representatives from Eyre's Peninsula, two from districts north of the Burra, two from the district south of the Burra to Adelaide, two from the Pinnaroo district, two from the South-East, two from the Hills, and two representing the Irrigation Areas ; this body to draw up a plan of experiments to be recommended to the Branches in the respective districts during the present year."

Professor Perkins said the difficulty was that a body of men representing different districts were going to commit individual districts to a certain policy. He thought the Congress could adopt the view that this work would be advantageous, but the fixing of the practical work should be determined at the next Conference of Branches in the respective districts. He was afraid the body suggested was not the best to settle the character of the work to be done.

Mr. R. Carter (Canowie Belt) agreed with Professor Perkins.

Mr. Nicholls explained that the proposal was for the central committee to suggest only, and that discussion could still be provided for at country Conferences if necessary. The motion was carried, and a committee consisting of the following gentlemen was appointed :—Northern Districts—W. Gum, Amyton ; S. Eyre, Georgetown. Lower North—J. P. Pontifex, Paskeville ; E. H. Gray, Riverton. Hills and Fruitgrowing—C. Ricks, Cherry Gardens ; S. O. Smith, Angaston. Irrigation Areas—H. S. Taylor, Renmark ; T. G. Rogers, Waikerie. District East of Murray—W. B. Russell, Loxton ; A. J. H. Koch, Lameroo. South and South-East—S. H. Schinckel, Naracoorte ; C. P. Hodge, Tintinara. Eyre's Peninsula—T. Masters, Roberts and Verran ; E. M. Page, Green Patch.

The Committee met at a later hour and drew up suggestions for consideration by the Branches, and arranged to have same sent out at an early date.

CONFERENCE OF HILLS BRANCHES.

The Annual Conference of the Hills Branches of the Agricultural Bureau was held at Mount Barker on the 13th instant. In addition to the Hon. T. Pascoe, M.L.C. (Minister of Agriculture), the following officers represented the department :—The Director of Agriculture (Mr. W. Lowrie, M.A., B.Sc.), the Horticultural Instructor (Mr. Geo. Quinn), Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), G. R. Laffer (Chairman), and G. G. Nicholls (Secretary Advisory Board of Agriculture). The chair was occupied by the President of the local Branch, Mr. H. N. Bell, and the undermentioned delegates attended :—Strathalbyn—A. Beviss, P. A. Cockburn ; Morphett Vale—E. E. Hunt, F. Rosenburg, L. F. Christie, A. C. Pocock, H. V. Sprigg ; Blackwood—A. A. Magarey, A. W. Magarey, H. E. Sibley, C. G. Savage, W. L. Summers ; Meadows—W. Phillips, G. E. Ellis,

G. T. Griggs, Pearson; Woodside—A. S. Hughes, G. J. Sampson, F. Baldock; Cherry Gardens—G. Jacobs, C. Ricks, G. Hicks, J. Lewis, A. Broadbent, H. Jacobs, S. W. Chapman; Mount Pleasant—H. A. Giles, D. C. Maxwell; Clarendon—E. Dunmill, T. B. Brooks, A. Phelps, J. Piggott; Uraidla and Summertown—T. H. Collins, E. Hawke, W. Squires, H. F. Johnson; Longwood—W. Nicholls, E. J. Oinn, E. A. Colbey, E. A. Glyde, A. F. Furniss, W. H. Hughes; Ironbank—J. T. Morgan, W. H. R. Coates; Port Elliot—H. B. Welch; Gumeracha—J. Monfries; Narrung—W. L. Williams; Mount Barker—A. Watson, H. Coppins, H. Jones, J. A. Ferguson, L. S. Hughes, J. Bunnett, B. Bunnett, P. Stephenson, F. Simper, J. C. Gallasch, W. Pearson, C. B. Pope, R. C. Hollamby, J. Morris, B. Fuller, W. G. Wilks, W. E. Daddow, F. R. Follett, J. Pope, H. A. Monks, J. Cleggett, B. Stephenson, B. H. Fiedler, J. E. Smith, W. E. Davis, J. Coventry, F. Adams, A. D. Wilkinson, D. L. G. Monfries, H. N. Bell, C. Miels, W. Stephenson, J. F. Moore, L. A. Cockshell, A. B. Blades, L. Cornish, E. P. Mappley, E. Schmidke, G. Milne, J. Frame, C. Liebelt, P. F. Liebelt, J. F. Liebelt, H. Pope, Dr. Scott.

OPENING ADDRESS.

The Minister of Agriculture said he had opened, he believed, more Conferences of the Agricultural Bureau during the last two years than any previous Minister had ever dreamt of opening. He had been from one end of the State to the other in pursuance of that duty, and had found great pleasure in the performance of it. Every conference had represented a vastly different class of country in the matter of soil, climate, and rainfall; hence the difficulty of laying down hard and fast rules for the guidance of the primary producers in all. Compared with many other parts of the State, the people in the hills had much to be thankful for. For example, on his own farm near Terowie this year the rainfall had not totalled 5in. They would easily recognise the impossibility of growing under such conditions crops of the character that could be successfully raised in the hills. Coming up from the city by motor car that morning, he had been much impressed with the obvious fertility of the soil, and the general atmosphere of prosperity, and could not help making a comparison with the North, as he saw it a fortnight ago. It seemed as though he had been transferred to a country altogether different. The opportunities for successful production of various kinds in the hills were better probably than anywhere else in the State. There was always a certainty of some return. He had no doubt that as a result of the adoption of the most scientific methods of cultivation the carrying capacity of the land would be materially improved, and the population would increase many times over. In the Far North the men on the land were dependent very largely upon one crop—wheat. In the Lower North—probably the best wheat-growing area in the State—there were greater possibilities in respect to other crops, but not nearly such excellent possibilities as they had in the hills.

Profitable Industries.

Apparently, if there were one thing likely to prove a profitable occupation in South Australia, owing to the needs of other parts of the world, it was the production of special fodder crops for the purposes of stock-raising. Consumption in the older countries was rapidly outstripping the supplies, especially of meat. Higher prices were inevitable, and promised for local stockowners a better opportunity of reaping benefit than they had ever before enjoyed. Without doubt, it would pay the farmers to give increased attention to growing fodder crops and marketing them on the hoof. His observations in regard to meat applied also to cheese, butter, and other dairy produce. The keeping of stock and the proper feeding of them would not only yield a direct return, but would assist to enhance the fertility of the soil. Messrs. Pope Brothers had provided a splendid illustration of the possibilities of soil improvement, for, by judicious treatment and well directed enterprise, they had converted a seeming waste into a very fertile area, which gave promise of enormous crops in the future. So far as fruit culture was concerned the hills had a tremendous advantage over the irrigation settlements on the Murray, where the growers were handicapped by big expenses, including the payment of about 30s. an acre per annum for water. In the hills they had sufficient natural precipitation, with efficient cultivation, to grow good crops with almost absolute certainty. Some people asserted that the limit of profitable production had been reached in the case of apples, but Tasmania, which was the largest grower in the Commonwealth, was still steadily extending the areas under trees. That did not suggest any fear regarding over-production. Personally, he was convinced that there was an important future before the State, not only in the matter of meat and dairy products, but also in connection with fruit, especially as the facilities for transportation were increased, and the difficulties in the way of proper temperature, &c., on ship board were overcome. He believed that the producers in the hills were fully alive to the privileges which they enjoyed, and that they would do even more than they had done in the past to bring the name of South Australia to the fore. In conclusion, he emphasized the value of such gatherings as that, and contended that while they were continued the men who attended them would never get behind, but would ever improve in their methods, augment their output, and increase their prosperity. He wished the Conference and the primary producers generally every success.

Thanks.

At the instance of Mr. J. Pope, the Minister was accorded a hearty vote of thanks

LIVESTOCK AND SOIL FERTILITY.

In introducing a paper on this subject Mr. H. V. Sprigg, of the Morphett Vale Branch, said the dearly-bought experience of American farmers on virgin soil showed that the continuous growth of cereals tended to exhaust the fertility. It behoved farmers in this State to profit by this, rather than wait until they were taught the bitter fact. The paper read—"The true principle of good farming is to get as large a return from the land as possible, at the same time maintaining, if not increasing, the fertility of the soil. If all the crops grown on the farm are carted to market and sold the farmer is selling the fertility of his farm, and such a system must end in depletion. To maintain its fertility he must turn his farm into a factory and change the raw products into milk or meat, the by-products being returned to the land as manure. Animals are a very important factor in soil making, and the farm that is well stocked has soil makers continually at work maintaining its fertility. Rotation of crops and live stock systematically worked are absolutely essential. Farming cannot be carried on successfully by drawing on the capital any more than any other business, and because the capital is represented by the fertility of the soil, that it has taken ages to accumulate, is no excuse for squandering it in a lifetime—you cannot eat your hen and go on selling her eggs. The factors underlying soil fertility are very complex, much is known, but probably more is unknown. To determine the amount of plant food by analysis does not help much, even poor soil has enough potential plant food to grow hundreds of crops ; it is only immediately available plant food that counts, and that cannot be determined by analysis, as it depends on the synchronising of so many conditions, such as tilth, moisture, climate, humus, lime, bacteria, and many others. The farmer cannot go on increasing his yields by simply putting the required plant food into the soil in the shape of fertilisers any more than he can increase his butter-fat yield by feeding his cow on machine oil. He must let nature work in her own method, and all he can do is to provide her with favorable conditions, as far as he knows them, and is able. Both experience and experiment have shown that certain factors that he can control or provide are imperative in addition to plant food ; the most important are a good tilth, humus and lime. These, with the requisite moisture, allow a free circulation of air, and provide conditions required for the development of bacteria, which are important agents in rendering plant food available. Other practices are injurious : for instance, to continually grow the same kind of crop, sell the grain, and burn the stubbles will spell diminishing yields, and even with fallow and fertilisers must ultimately burn up the humus and consequently the nitrogen. The soil will also become intractable, full of weeds, difficult to work, and a physical condition inimical to fertility will ultimately arise. Whatever the reasons may be, 'land that has become 'sick' to the same crop will respond to another kind, so, to obtain the best results, rotation of crops must be adopted. The essential factors in any rotation are deep and shallow rooting plants alternately and the inclusion of a legume. Different root systems feed in different layers of the soil; also the decaying root and leaves of the one are excellent food for the other, and the legume insures the nitrogen supply. Rotation is also the best method for preventing disease and insect pests. All pests, whether parasitical or insect, are specialised feeders, and by increasing the interval between the host crop it is rendered difficult, if not impossible, for them to exist. As an instance, 'takeall' can be cured by the adoption of a system of rotation. As a natural corollary one of the greatest advantages derived from a rotation of crops is that it renders possible the keeping of live stock as a means of secondary production of meat and milk, the best paying products of the farm, returning the by-products to the land in the form of manure. The great bulk of plant material is drawn from the air, only about 3 per cent. of the mineral matter being taken from the soil, and, of course, the water—about 72 per cent.—the remaining 25 per cent. being derived wholly from the atmosphere in the form of carbon. If, as in green manuring, the whole of the plant is returned to the soil, it will follow that the soil will be the gainer by just so much material as was drawn from the air. When, however, it is fed to farm animals it is found that 50 per cent. of the dry matter reappears as manure, the rest being used up in animal functions and tissue. If the crop is fed off, say, by sheep, the farmer will save this 50 per cent., less the small portion of ammonia lost by evaporation. When stored in manure heaps the loss may amount to anything from 20 per cent. to 50 per cent., according to the method of storage, treatment, and use. There are other aspects of this question it will pay to consider. Australia is one of the most favored countries in the world for live stock production, and this particular district is not the worst of it. The mild climate means that less food is consumed in producing heat, that stock is healthy, matures quickly, and there is not the cost of winter stabling, the stock running and getting their own living, as it were, all the year round. These advantages are so little valued as special, that many refuse not only to grow any fodder crops, but also to conserve any of their waste products, such as straw and chaff, so that when they have an adverse season their stock is starving, as it is in many places to-day. An instance of the favorable conditions for stock in Australia is the command of the wool market of the world; and when it is realised that, with the exception of South America and perhaps South Africa, in the other countries the live stock, if not decreasing, is not increasing at the same ratio as the population, and most of them do not produce enough for their own consumption, Australia's importance in the meat market of the world may be seen. Distance is now measured not by miles but by time, and by utilising cold storage this State can put its meat on the European market in perfect condition in a few weeks. My object in writing this paper is not simply to make quasi-scientific statements of the principles of agriculture and fertility, and of facts that may seem platitudes, but to emphasize the fact that live stock and meat production are not given the important position on most farms that they deserve. A few sheep are kept as scavengers, with a few cows and pigs as side lines, but they should have the primary position. The bulk of the farm produce should walk to market, the residue being returned to the land. This does not mean giving up cultivation and tillage and turning stock into the paddocks, sitting on the fence watching them starve, and then dosing them for dry bible. It means more and more varied cultivation, more intense farming, with seeding spread over a longer period. Some will say they cannot grow feeding crops, and that the summers are too dry to grow summer feed without irrigation. Nature has, however, answered this, unfortunately for many of us, by the luxuriant growth of stinkwort and other noxious weeds with which fallows and grazing lands are covered during the summer. What are to be grown is another question. Among legumes the value of peas as a forage crop for fattening freezers is undoubted ; and lucerne in many places is successfully grown ; also rape and mustard and thousand-headed kale. Mangolds and beets among the root crops should be tried. With the barley crop lucerne and clover may be sown with good results. On this question of what to sow hangs the main object of this paper. I want to throw out a suggestion and make an appeal to this Conference and to all the Branches of the Agricultural Bureau. What I suggest is that each Branch make experiments and trials with fodder crops under field conditions by its members, with the object of finding the most suitable rotation for its district to increase the stock carrying capacity of the farm. By co-operating in this manner, different members trying different crops, a lot of valuable information can be obtained in a short time which it might take an individual a lifetime to acquire, and each district would work out its own salvation ; if successful the benefit would be inestimable. I referred previously to the luxuriant growth of stinkwort and other weeds as proof of the capacity of our soil and climate to sustain summer growth without irrigation. Here may be a field for research, and if any kindred plants are edible for stock, by proceeding on the lines of Mendelism and Luther Burbank an exceeding valuable fodder plant might be discovered. The particular rotation or live stock best to use I have not attempted to say. This depends on the district, the farm, and the man. What I want to emphasize is the underlying principle that rotation of crops and live stock will increase the profits and the fertility of the farm."

Mr. Giles (Mount Pleasant) recommended all growers of lucerne to cut and carry off the crop. If they fed it off the crowns would be eaten. Every three years or so it should be given a scarifying and top dressing and it would last for a very long time.

Good discussion followed, in which the opinion was freely expressed that the production of live stock demanded attention in the hills districts.

SOME SEASONABLE POINTS IN THE CARE OF THE ORCHARD.

Mr. Geo. Quinn (Horticultural Instructor) delivered an address, in which he said—"Although the occupier of a fruit garden can never find an excuse for being idle, some periods of the year find him more busily engaged than others. The advent of spring, when all nature starts into renewed activity, is one of these busy periods. In addressing myself to this subject, I propose to deal with one or two phases of orchard work that are at present exercising the minds and muscles of fruitgrowers. The return of the sunshine in increasing strength not only causes weeds and grass to spring with almost magical rapidity into flower and seed, but it increases evaporation vastly and threatens to leave the ground baked and dry. The portion of the land which, during the winter, has been besodden with moisture soon becomes the hardest and driest part of the orchard. The realisation of this fact leads one to inquire why these opposite conditions in the physical composition of the soil so quickly follow upon each other with the change of the season, and how can these extremes be corrected. The reason our orchard lands in these ranges where the rainfall exceeds, say, 27in. per annum become sodden in winter is that they are mostly underlaid by close-grained clays which do not readily permit the rain to pass through their strata, and consequently its principal methods of escape are by flowing off at the surface or evaporating therefrom. It is possible these remarks have not a fitting application in the present season, but they will apply to the average year's experiences. When land becomes waterlogged the roots of the trees stand through the winter in an area which has become devoid of oxygen, and the result is they perish or to a great degree lose their power of resistance and fall an easy prey to bacterial and fungoid agencies which are always on hand waiting to decompose their tissues back to the original elements. The fruit tree thus affected does not usually display any evidence of the injury until the return of spring or early summer, when, having started, its buds soon use up the accumulated nutriment stored from the previous season, and after the first effort at leaf and blossom its vitality is stayed. In advanced cases it simply dies, or in others less complete progress in leaf and shoot formation waits upon a fresh root growth from those portions of the root system—usually near the surface—which have survived. The obvious remedy is to prevent that over-saturated condition arising at any rate in the main rooting area of the trees. The only feasible method whereby this can be attained is by under-draining the area so affected. It does not follow that the whole of an orchard area needs under-draining, neither should we cling to the fallacy that because the surface is sloping that it is necessarily exempt from over-saturation. As far as my observations go the springs are largely found on the hillsides, showing clearly that the surface strata is not continued down in parallel layers. The suggestion I have to offer is that in the orchard wherever water oozes from the slopes those spots should be carefully marked and drains laid in during the summer or autumn season whenever time permits. The effect of this want of a free passage for the winter's rain through the soil is not by any means necessarily seen upon orchard trees during the first few years after planting them. On the contrary, the evil effects appear to accumulate with the reaching out of the roots for a greater feeding area, and the increasing demands for nutriment made by the enlarging tree as it bears its crop of fruit. Of the various kinds of underdrains none are so truly effective as those formed of burnt clay pipes laid end to end on an even fall. These are now procurable in the State at about 63s. per 1,000ft. for 2in. diameters, which is large enough for most purposes. This means about five chains of drain pipes for £1. The cost of making the trenches and laying them in position will depend on the nature of the land for trenching and the depth they are inserted. This, in most soils, will be not less than 2ft. 6in. The collecting drains should not be carried anything like straight down the slope, but rather take an oblique course so as to intercept the percolation of a wider area. To use a homely illustration, they should " fishbone " between the rows of trees into the outlet or main drain. Probably the most important consideration in pipe draining is to make the bottom of the trench where they rest butted end to end with a perfectly even fall, as any undulations must inevitably result in the silting up of the pipes. There appears to be some misapprehension in the minds of those who have not used drain pipes, respecting how the water enters the drain. When we are assured that the drains only start to operate as the soil water rises from beneath and enters through the joints, we can realise that the soil is kept oxygenated to the full depth the drains have been inserted ; hence the deeper the drains the deeper the soil is sweetened and kept suitable for root extension. Land that is trenched or subsoiled will gradually consolidate, but a properly drained area retains its wholesomeness as long as the drains remain operative, as each winter's moistening swells the soil plots between the drains, and each succeeding summer's drying out shrinks it again. This aerating action breaks down the particles, making a larger and more continuous area of inter-granular spaces, somewhat erroneously called capillary spaces. It is in these interstices the sweet or wholesome soil moisture is held and moves, and hence it is that the drained soil is not only drier in winter than non-drained land, but it is also moister in summer. This is not a mere platitude, as the former can be tested by driving a team over the land, and the latter by the simple process of digging a hole into the subsoil and examining it for moisture. Although well-drained soils hold their capillary moisture longer into the summer than those not thus treated, the best results cannot be expected without the surface of the land be treated to suitable tillage. On the open country less favored with a good rainfall than these districts the necessity for getting the surplus moisture away from the trees in winter is almost entirely absent; in fact, on the contrary, there the land is opened up as early in winter as possible to admit the rain evenly to the sublayers from whence, by certain forms of summer tillage, its escape is retarded. The steeper character of the orchard land in the hills renders it liable to " wash " or " slide " if treated in this manner, and the average hillside orchard with a good rainfall is, doubtless, best left in grass and sod until the bulk of the winter's rain has fallen. There appears, however, much danger that the erstwhile sodden land may, with the quick return of summer, become so rapidly baked on the surface that the tillage operations are difficult to perform in a satisfactory manner. There is very little doubt that fruit trees in the hills suffer much more from the effects of a protracted spell of dry weather than do those of the plains, which are apparently more inured to harder fare. In consequence of this danger, there is much to support the opinion that whilst orchards in the hills do not need winter tillage they require good attention in this respect in the spring and summer, more particularly when the winter's rainfall is below the average and the summer proves dry. It is pertinent to ask what is good tillage in spring and summer? I hold the opinion that this is best answered by a good ploughing or digging of moderate depth, followed immediately by a pulverising implement such as is found in the various forms of cultivators. The ploughing is to bury the weeds and aerate the surface and make possible the subsequent scarifyings which break the furrows down to as fine a state of subdivision as possible, and to spread it evenly and flatly like a dry blanket to prevent the moisture from the sublayers finding a direct contact with the atmosphere. Whenever enough rain falls to consolidate this surface through to the unpulverised soil below, the surface should again be stirred to break that contact. May I suggest a modification of this summer practice along the lines of what is expected from the trees. If they are quite young and strong growth is desired the summer tillings may, with advantage, be persisted in through to the autumn whenever needed. On the other hand, if the trees are mature in stature and inclined to too great vigor as opposed to fruit setting, after mid-summer it may be wise to scarify somewhat tardily with a view to permitting the escape of moisture and thus ensure an earlier ripening of the wood and leaf growths. Again, if the trees are carrying heavy crops their demands upon the soil moisture are greater and tillage should be persisted in to secure the best sample of fruit. Sometimes, when the possibility of ploughing has become dependent upon a soaking rain—perhaps late in the spring—and the soil is likely to bake quickly in the overturned sod, it is found desirable not to delay the pulverising until the whole area is ploughed. I have seen excellent work done by running ordinary harrows every few hours across the land which has been ploughed, so as to prevent crusting and subsequent lumpiness, which means an ineffective mulch unless a heavy roller be used prior to scarifying. Whilst upon the tillage of the land largely depends the possibility of keeping the trees in health and the production of a profitable yield, these operations may, unfortunately, be nearly all wasted if the various animal and vegetable enemies of the tree and its fruit are not controlled. With the return of the leaf, the blossom, and the fruit, awaken into activity those foes of the orchardist. The codlin moth caterpillar, which has lain dormant in its snug cocoon, has felt the quickening touch of the sun's warmth and changed into the pupal or chrysalis stage, and as the young fruits on the pear and apple begin to be seen amongst the foliage the moth breaks its way out of the pupa case and cocoon and emerges into the light of day to fulfil its functions of reproduction. With the eye of faith, founded on accurate observation, the fruitgrower sees this insidious foe, guided by instinct, depositing its eggs close to where its young, when emerging weak and tender from the egg, can find, without assistance, the means of sustenance which is afforded by the fruit. This insect, which is a native of Europe, doubtless ravaged the apple orchards of those old lands from the time when the apple became an edible fruit ; but with the exception of catching a few odd, fully fed-up caterpillars which had done all the damage they could in their generation, no genuine attempt was made to control this pest until in the new land of America someone connected up the life history of the insect and found its vulnerable stage and formulated a remedy thereon. The psychological moment in the fight against this pest opens with the setting of the fruits upon the apple and pear trees, but it only ends with the harvesting of the crop. Modern science and practice has assured good results when these newly formed fruits are sprayed with an effective poison, such as arsenate of lead, and two or more sprayings follow along upon this early application, the best results accruing in the case of late ripening varieties when the latest spraying is given towards the end of January or early in February. Many growers now abandon the use of the bandage trap and the cleaning of the stems of the trees ; but, although somewhat troublesome, it is questionable whether this is wise. The bands afford a good index to the value or effectiveness of the spraying, and the stray caterpillars which avoid being poisoned should not be afforded a safe refuge about the stems or bark of the trees.

Fusicladiums and Shothole Fungi.

Among fungus pests which exercise the minds of fruitgrowers in these hills the most prominent are the fusicladiums, or " black spots," of the apple and pear and the shothole fungi of the plum and cherry. The former, it has been demonstrated, are most vulnerable in the spring with the bursting of the buds and the setting of the fruits, and it is at this spring season that an effective coating of fungicide, such as Bordeaux mixture, has the greatest preventive action, for up till now it is a question of annual prevention and not cure upon which we can rely only." The making of Bordeaux mixture, he considered, was an important factor. Arsenate of lead was procurable from chemists, but Bordeaux mixture required to be manufactured by the orchardists. With the usual method adopted in making this mixture there was generally an excess of lime. This was very often the direct cause of injuring the foliage and the fruit. Pickering thought that this should not be used, and he contended that by using lime water only they did not get this surplus coating of lime, which interfered with the action of the carbon dioxide on the copper compound which was the actual fungicide in the mixture. With regard to application, he felt certain that the value of the mixture did not depend on the strength that they used, but rather on the time at which it was used. It had been shown by laboratory tests that a fungicide much weaker and consequently cheaper than that generally used would destroy the germinating spore of the fusicladium. He strongly urged them to use it at the bursting of the flowers, and again at the setting of the fruit. Shot-hole was not controlled in the same way as they controlled the curl leaf of the peach. By using Bordeaux mixture in the autumn they could check injury to the plum, apricot, and cherry. It was prevalent at the present time in the young shoots, which appeared to have died under the influence of fire. The attack began before the bud began to emerge from its winter covering.

QUESTIONS.

Mr. H. Jones (Mount Barker) asked whether it was possible to prevent attacks of curl leaf by spraying.

Mr. Quinn replied that this could be prevented in this way. Curl leaf was probably the simplest of all the fungi to control. They had carried out very exhaustive tests at Blackwood for three years, going to the trouble of picking the affected leaves from the trees. Best results were obtained from the use of 1¾lbs. of washing soda and 1lb. of bluestone, dissolved separately and mixed with 10galls. of water.

Mr. E. T. Grigg (Meadows) asked if the Bordeaux mixture could be used for black spot at the same time that they were using arsenate of lead.

Mr. Quinn said arsenate of lead and Bordeaux mixture might be put on with the one operation if they were compounded separately. The Bordeaux mixture could be used by itself when the flowers were bursting, combined with the arsenate of lead when the fruit had set, and used a third time, by itself, if there were a likelihood of the spots appearing. It was a question of having a thin film of copper upon the fruit.

Mr. W. Pearson (Mount Barker) asked if there was any known remedy for black spot in the walnut.

Mr. Quinn said that although this disease outwardly resembled the black spot of the apple and pear, it was due to a bacterium and not to a fungus. A bacterial disease operated in the sap, and up till the present no good had resulted from any spray or outward application to a bacterial disease. They should begin by growing the trees from clean stock. The best plan was to rigidly rake up and burn all the diseased fruit and cut away the damaged points of the shoots and burn them.

Mr. B. Stephenson (Mount Barker) desired to know the best time at which to spray peach trees badly affected with aphis, and would the spray destroy the bees ?

Mr. Quinn replied that effect on the bees depended on the spray that was used. Bees were not affected by the contact spray used for aphis ; they were destroyed by poison. If they sprayed with poison when the trees were in full bloom they might kill the bees. The best spray for aphis was made of tobacco and soap wash. If they put in one pint of resin wash to the gallon and sprayed it on warm it would kill every peach aphis that it touched. The reproduction of the aphis was so rapid that it was necessary to follow it up with three sprayings, say, every other day. It would not make the slightest difference whether the spraying was done in the morning or the afternoon.

Mr. A. Phelps (Clarendon) mentioned the case of an orchard of apricots of about 100 trees which were heavily pruned this year. Six of the trees were left unpruned. This six were bearing good crops of fruit, whilst the balance of the trees were bare. He asked for an explanation.

Mr. Quinn said it appeared as though most of the fruit wood of the pruned trees was cut away. There was an advocacy of leaving the apricot with longer leaders than was generally the practice. This had resulted in a bigger setting of fruit. The work had not been carried on for sufficiently long in the non-irrigated districts at any rate for them to tell what the final comparative results would be, but it stood to reason that if they left a larger amount of fruiting wood they would get a bigger setting of fruit. If they cut the leading branches the tree attempted to repair this injury, which resulted in excessive growth, which was opposed to the setting of fruit. Possibly the gumming of the buds had something to do with the non-setting. This was almost entirely due to the operation of a fungus. Personally he could not see that it would affect pruned trees more in proportion than those unpruned. They should attempt to determine the method that would give the best fruit for the longest period and follow that.

Mr. W. Nicholls (Longwood) asked whether the mixing of Bordeaux mixture and arsenate of lead would not result in the mixture becoming too dilute.

Mr. Quinn said that in liquefying the arsenate of lead and preparing the Bordeaux, if they were mixing, say, 50galls. they should liquefy 2lbs. of arsenate of lead in a small quantity of water and pour it into the tank. The Bordeaux, after being prepared in a small volume of water, should also be poured into the tank and sufficient water added to make the 50galls.

Mr. A. J. Furriss (Longwood) thought that the fruit would become russeted as a result of these sprays being mixed and put on together.

Mr. Quinn said this had not been proved. Experiments at Lyndoch had revealed fruits in unsprayed rows as russeted as those borne by the trees in sprayed rows. The skin of the apple might be russeted by simply spraying with water, under certain weather conditions.

Mr. G. R. Laffer (Chairman Advisory Board) enjoyed the practical paper of the Horticultural Instructor. He had had some experience in these matters. In digging trenches for drainage he found that these could be done very economically with a pick possessing a double-tined end, the tines being spaced 4in. or 6in. apart. In addition to this it was necessary to have a scoop, somewhat after the style of a large fish-hook. With this an even surface could be obtained on the bottom. It was frequently laid down in text-books that orchards should be ploughed in the autumn and spring or summer. This should be determined by the district. If they ploughed their land in the autumn it would set down with the winter rains. Whether they should plough away from the trees was also to be determined by the district. He made it a rule to make the first spraying for the moth as effective as possible. He sprayed as soon as the petals fell, and again in eight or ten days' time. He believed in bandages; their use was a practice that went side by side with spraying. It was absolutely essential, especially in older orchards, to keep the stems free of rough bark. There was no doubt that shothole was more prevalent in the hills this season than it ever had been before. He had been spraying for this for several seasons, and he had had fairly good results from early winter spraying. The growing of peaches in the hills absolutely depended on winter spraying. They had wet climatic conditions, and there was a tendency for the buds to gum in the winter. This applied equally to apricots. One or two sprayings just about the time the foliage was dropping off would control this. He attributed the magnificent crop which he secured this season to this treatment. He generally sprayed apricots three or four times, and usually secured good crops of clean fruit. In growing certain early varieties of peaches they adopted the practice of never pruning the trees until they were in bloom, because if they were pruned in the ordinary way practically all the fruit buds the trees bore would be cut off. The same thing applied to apricots. To grow this fruit successfully in the hills it was necessary to spray just about the time the leaves were falling, the ordinary strength of spray being used.

GRASSES.

Mr. E. J. Oinn, of the Longwood Branch, read the following paper:—"In this district and the surrounding country, where sheep-raising and dairying are carried out, something about grasses, which might improve the carrying capacity of the land, should be of value. Doubtless, some will think that the feeding values of the grasses on their land at present are sufficient without trying anything else; but the result of a few experiments might improve the carrying capacity a good deal. The best grass plant that I know of, and which has given me the greatest satisfaction on moderately damp and fairly rich soil, is called Guinea grass. It is a vigorous and quick grower, and will stand mowing off three or four times a year or a moderate amount of grazing for seven or eight months in the year. The two which have proved next in value to Guinea grass are Cocksfoot and Prairie grass. I worked up a piece of hillside land of poor, sandy, stony soil, 3in. deep, about six years ago, and applied bonedust at the rate of 2cwts. to the acre. The season being good, I put the plants in rows, 9in. apart, by 6in. in the rows. They stooled out so that they made one broad row of solid grass about 8in. wide, and it grew to a height of 3ft. 6in., as thick as it could stand. When the seed ripened I collected it to plant elsewhere. After I collected as much seed as I wanted, I let the cow in on to the patch and she did extremely well on the straw. I sowed the seed which I collected on some gully land, with the object of getting it to grow for yearly crops of hay and greenfeed, without having to work the land up every year, so I gave it a dressing of bonedust, 1½cwts. to the acre, with the result that I had an abundance of greenfeed, and afterwards a crop of hay, which would go about 3 tons to the acre. I waited until the young grass got a fairly good start again, then gave it another dressing of 1½cwts. of bonedust to the acre for the crops of greenfeed and hay for the next year, and I continued to do that for four years with success. The grass at the present time, after a period of five years, having been continually cut for green feed and hay, looks as strong and healthy as ever. I grazed a cow on the plot on the hillside where I raised the seed for a period of three years continually, with the result that it was killed outright. Cocksfoot and Prairie grass make good feed for horses and cows as hay or chaff if cut just as the bloom has fallen ; but if left until the grain gets into a dough stage it seems to become hard and woody in the stalks and the animals will not eat it. The land on which I sowed the seed consisted of good gully black soil which could be irrigated as occasion required, so that it was capital for producing the results stated above. I planted some Cocksfoot and Prairie grass on hillside land among some fruit trees with the object of trying to produce annual crops of hay without having to work the land up every year, but by the addition of 2cwts. of bonedust to the acre I could only get moderate crops for hay every season, which I consider fairly successful ; but I noticed that when the cow was fed on the chaff cut from Cocksfoot and Prairie grass hay, with the addition of a little bran, the milk yield was better and the cream thicker than when she was fed on the same quantity of bought chaff and the same quantity of bran. Another grass which I have grown is *Panicum Crus-galli*. In the first place this came up amongst a crop of growing vegetables, and when the weather warmed up at the beginning of summer it grew with such rapidity that it killed out the vegetables ; but being short of greenfeed at the time, I allowed it to grow to a height of 4ft., when it came into flower ; then I used it as greenfeed. This grass, although a great curse in a vegetable garden, is a good plant for the production of summer greenfeed, as in six weeks from the time the plant gets above the ground it produces a crop of greenfeed on good moist soil, from 2ft. to 2ft. 6in. in height. There is one great drawback, however, it is only an annual, the seed sprouting into growth as soon as the sun warms up the ground in the spring, and growing through the summer till the first general frost comes; then it is killed outright, and does not grow again until the following spring. This makes it not nearly so valuable, to my mind, as a perennial, as it only grows about five months in the year, and then it is done. I grew *Phalaris commutata* and Chewing's Fescue together for greenfeed and hay, but they did not produce anything like the quantity or the quality, either as greenfeed or as hay, being too slow in growth for greenfeed—the *Phalaris* growing too coarse and hard for hay, the Fescue growing too thin to give any profitable results. I planted a mixture of Guinea grass and English Meadow Foxtail grasses on good soil, where it could be irrigated in the dry, summer months, with surprising results, being able to get several cuts of greenfeed and two crops for hay every year, and I can safely say that some of the best and sweetest smelling hay was produced from that plot of Guinea grass and English Meadow Foxtail, the crops averaging about 2ft. high. These experiments have been carried out on a small scale, producing fodder for only one cow and sometimes a horse, so I cannot give any estimate of how they would answer on larger areas, or how many sheep could be grazed to the acre; but I thought that this being a dairying and sheep-raising country the result of my experiments might be useful."

DISCUSSION.

Mr. F. Dadow (Mount Barker) asked whether the writer of the paper had had any experience with Japanese millet.

Mr. Oinn had tried this, but was not very satisfied with it as a fodder crop, as it could not be turned into hay successfully. It grew well, but owing to the quickness of its growth had to be used very rapidly. The stalks grew too thick and the hay went mouldy. It only seemed to stand one general cutting.

Mr. Stephenson (Mount Barker) had found *Phalaris commutata* a very good frost resister. It would stand feeding off.

Mr. T. Jacobs (Cherry Gardens) asked at what stage should Prairie grass be cut for hay. If it grew anything like to maturity it became very coarse. He also desired to know whether Mr. Oinn had had any experience with Cow grass.

Mr. Oinn said the first year he tried to make hay from Prairie grass he cut it in the same manner as they treated wheat and oats. It made a good smelling hay, but was too hard. The following year he cut it just after the flower had fallen, and the hay was good. He could not get such good results from Cow grass as from the other grasses mentioned. Guinea grass grew somewhat like the natural grasses of the hills, but it did not have such a stiff, ribby leaf. The seed was very small, and the plant also grew from roots.

Mr. Jones (Mount Barker) had chaffed Prairie grass for horses after having thrashed the seed out of it.

Professor Lowrie thought the paper a very practical one. It was one that opened up many questions that could be profitably thought over in connection with the hills district. He indorsed what Mr. Oinn said about perennial *Phalaris*. The general opinion of those who had tried the grass in South Australia and in other parts of Australia was that compared with *Paspalum* and Rhodes grasses it was the best of the introduced grasses. He was inclined to the same opinion. Of Prairie grass and Italian rye grass he had had experience. There was no doubt that Prairie grass was one of the most rapid growing grasses in the winter time, and he had seen some very excellent cuts of hay obtained from it. In South Canterbury he grew Prairie grass and rye grass on the stubble ; cut it about this time, and put it into hay or silage stacks. It was used to fatten large numbers of cattle. On the general question as to whether they could get better results with artificial than natural herbage, he was not prepared to give an opinion. If the cost of seed and the cost of cultivation in a good many cases, and the constant care that was necessary in order to get the best out of them, were expended on the natural grasses, the total grazing capacity, although probably not the hay capacity, would be perhaps not greater in the one than in the other. This was a matter that had not been worked out, and it would take many years to determine. Mr. George Riddoch had spent a good deal of money in the South-East in working it out, chiefly with perennial rye grass and trefoil. His manager was of the opinion that the natural herbage paid better. At the same time there were certain of the grasses which, by saving, they could get to grow bulk enough to cut for hay, which gave them a great advantage in enabling them to carry stock over times when other things were done. The grasses that had been mentioned were the best. He considered Cocksfoot the very best of the English grasses ; it was better than perennial rye grass. The difficulty with it, however, was that it was of little use until it was into the second year. It was necessary to conserve it during the first year. Once it was fairly established it would stand throughout the summer.

Mr. Quinn mentioned that a week or so ago he had seen a fine strip of Cocksfoot continuing the second year in the heathy land in the Tintinara district.

Mr. Oinn eight or nine years ago had 15 roots of *Phalaris commutata*, which he planted on a square rood of land. He gave it 12lbs. of sulphate of ammonia and 6lbs. of bonedust, and when it had got a fair start added about 12lbs. of superphosphate. It was regularly irrigated during the hot weather. When it had been growing about three months it was 4ft. high and very thick. It was mown off, and grew to about the same height within a month.

Professor Lowrie, in reply to a question, said Yorkshire Fog was fairly good in the hills, although it was avoided in other countries. It was a weed, because stock would not touch it if there were anything else available. It was just better than want.

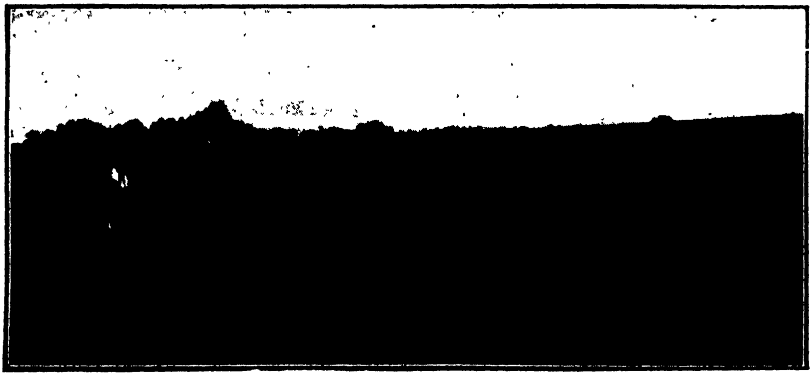
Mr. Nicholls (Longwood) disagreed. Whilst Yorkshire Fog was of little value in orchard lands, in the Mount Lofty district its feed value was good. It was considerably better grass than it had been 10 years ago. He had it growing on gully ground, and all through the summer he got a splendid growth, and the stock kept in good condition on it. They could not eat it right out.

Mr. T. Jacobs (Cherry Gardens) thought Yorkshire Fog a curse. It would completely kill out any other grasses, but there was no quality in it.

Professor Lowrie said one difficulty with Cow grass was that there was an insufficiency of seed. The natural red clover gave a much greater bulk of seed, consequently that which came into the market was rather the red clover than the Cow grass.

Mr. Monfries (Gumeracha) had had some experience with grasses. The two he favored were *Phalaris commutata* and Cocksfoot. The former would stand extremes of heat and cold. It was necessary to get the ground into good tilth, plough it again, put the small roots into the side of the furrow 6in. apart, as was done with potatoes, then cover them with the next furrow. The roller should then be put over the ground. Planting with the dibber was very expensive. Natural grasses were almost eaten out. It would pay them to manure and have smaller paddocks in which the cattle could be systematically fed. They would then reap a benefit from sowing these grasses.

(To be continued.)



Lucerne Crop, Turretfield.

THE WHEAT MARKET.

Reporting on the wheat position on October 3rd, *Beerbohm's Evening Corn Trade List* states—" According to a cable received from the St. Petersburg *Handels-Industrie-Zeitung* a few days ago, this year's Russian wheat crop is now estimated at, for the 73 Governments, 86,800,000qrs. The Central Statistical Committees' estimate of August gave the yield at 101,000,000qrs., so that the present unofficial estimate is over 14,000,000qrs. less than the earlier official one, and is even smaller than the official estimate for last year, which was 90,595,000qrs. The preliminary estimate of the Central Statistical Committee of July last was for a yield of 111,000,000qrs., and the reduction to 101,000,000qrs. in August was understood to be on account of the unfavorable harvest weather in July. As the weather since the early part of August has, on the whole, been favorable for securing the crop, it is not at all clear on what grounds there has been a further very large deterioration.

" As mentioned before the harvest in Canada is earlier than in 1912, also the railway facilities for moving the wheat from the farms are improving every year. The exports from Canada in the season ending August 31st last amounted to nearly 15,000,000qrs., and this season's exports are likely to exceed that quantity by 1,000,000qrs. to 2,000,000qrs. Cables from Toronto of yesterday's date state that 40 per cent. of the wheat crop is already threshed, and that the average yield throughout the Western Provinces is estimated at 20bush. per acre. On this basis the yield for the whole of Canada would be about 215,000,000bush.

THE WORLD'S VISIBLE WHEAT SUPPLY ON OCTOBER 1st.

Steamer Freights.—(November 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 31s. 3d. per ton (10d. per bushel), prompt or new season ; to South Africa, 27s. 6d. per ton ($8\frac{9}{10}$d. per bushel), prompt or new season. Parcels, Port Adelaide to London-Liverpool, or Continent, 25s. per ton (8d. per bushel) ; Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel) ; to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 31s. 3d. to 32s. per ton (10d. to $10\frac{3}{10}$d. per bushel), new crop ; South Africa, 26s. 3d. per ton ($8\frac{2}{5}$d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on November 1st—

BUTTER FACTORY.

There was a decided increase in the quantity of cream received last month, and the quality was excellent. The demand for butter was well maintained, but prices eased slightly. The present rates are—Superfine, 1s. 0½d. per lb ; pure creamery, 11½d. per lb.

A. W. Sandford & Co., Limited, report on November 1st—

BUTTER.—Supplies of butter and cream again increased during October, while prices in top factory and creamery butters are practically as high as they were a month ago. Best factory and creamery, fresh in prints, are selling at 11d. to 1s. 1d. per lb. ; choice separators and dairies, 9d. to 10d. ; store and collectors' lines, 8d. to 8½d.

EGGS.—There is no material alteration to record either in the position or in values, and prices throughout the Commonwealth remain stationary. Guaranteed new-laid hen, 8d. per dozen ; duck, 9d.

CHEESE.—There was a very heavy turnover during the month of October, both local and export traders purchasing freely. Present rates are from 5½d. to 6d. per lb. for large to loaf.

HONEY.—Buyers are still operating for prime samples at 3¼d. per lb., but second grades are neglected. Beeswax, very saleable at 1s. 2d.

ALMONDS.—Stocks are practically cleared, and the market is likely to open out strong for the new season's crop. Brandis, 6d. ; mixed soft shells, 5½d. ; hard shells, 3d. ; kernels, 1s. 5½d. per lb.

BACON.—The high prices previously reported continue to rule, and values are even a little firmer than a month ago.

LIVE POULTRY.—Rates have kept up remarkably well, supplies not being nearly equal to trade requirements. Good table roosters brought 3s. 6d. to 4s. each ; plump hens and nice-conditioned cockerels, 2s. 3d. to 3s. ; geese, 4s. 6d. to 5s. 6d. ; ducks, 2s. 4d. to 3s. 6d. ; turkeys, from 8d. to 11d. per lb. live weight for fair to prime table birds.

POTATOES AND ONIONS.—The weather conditions of the Adelaide plains this spring have been highly favorable to the growth of potatoes and onions. Heavy crops, and therefore moderate prices, are freely anticipated. There are still large quantities of old potatoes available, but many of these will apparently not reach the market this season. Onions—There is no alteration to report in this line, and the new season's crop is now delivering. Present quotations are—Potatoes, Gambier's, £3 2s. 6d. per ton of 2,240lbs. on truck Adelaide or Port ; 3s. 9d. to 4s. 6d. per cwt. in the market. Onions.—Gambier's, £7 5s. per ton of 2,240lbs. on truck Adelaide or Port ; new locals, 10s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of October, 1913, also the average precipitation to the end of October, and the average annual rainfall.

*No report received during the month of October. † Formal report only received.

Where Branch meetings are mainly occupied with the reception of reports of Congress by delegates these will be classed as "formal."

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

December 10th and January 14th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Coomooroo, October 10.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. G. B. Lillicrapp (chair), E. Brice, R. G. and A. Polden, W. Barber, R. Brice, C. Phillis, L. Avery, E. D. Kirkland, J. Polden, W. M. Robertson (Hon. Sec.).

Harvesting Machinery.—The Hon. Secretary, in initiating a discussion on this subject, advised members to prepare their machinery for the harvest several weeks before the work began. Mr E. Brice advised cleaning all bearings of oil and grease accumulations and filling the oilcups with kerosine. Mr. Lillicrapp recommended screwing up all nuts and bolts and to take care that the oil was running freely. Members were divided in opinion as to whether it was better to clean the bearings of oil accumulations immediately after harvesting or to leave these on during the time the machines were not in use.

Hookina, October 21.

(Average annual rainfall, 12in.)

Present.—Messrs. D. E. Madigan (chair), P. and B. Murphy, H. Huddleston, J. Henschke, C. F. Stone, P. Kelly, jun., J. Carn, S. Stone (Hon. Sec.), and four visitors.

Farm Improvements.—Mr. J. Henschke contributed a paper in which he said that the first essential in connection with an unimproved farm was the selection of permanent water. A bore could be put down more quickly and with less expense than a well, and when water was struck a windmill could be erected and a large storage tank provided. The property should be fenced with either wire netting or six wires, and the farm divided into small paddocks as soon as possible. Attention should then be given to the homestead, which should be comfortable. Where good holding ground was available a dam should be sunk in every paddock, as stock did better on rainwater. The household supply should be conserved in an underground cement tank. Fruit and vegetables should be grown, and no farm should be without a blacksmith's shop.

Quorn, October 18.

(Average annual rainfall, 13·78in.)

Present.—Messrs. R. Thompson (chair), Noll, Bury, Schulze, Brewster, Cook, Jago, Britza, Patten (Hon. Sec.).

Conservation of Fodder.—Mr. Noll read a short paper on this subject, in which he stated that during seasons when there was an abundance of feed and good crops, farmers should store up enough fodder to tide them over one or two bad seasons. Where there was plenty of herbage, wild oats, thistles, &c., a pit or stack of ensilage should be provided. An extra stack of hay, if not needed, could be sold at a high figure when hay was scarce in a bad season. Cocky chaff should be gathered and covered with straw. If the farmer used the harvester, the binder should be run over the stubble and the straw cut and stacked, which could be chaffed as occasion arose. Members generally considered the advice sound.

Tarcowie, October 16.

(Average annual rainfall, about 15½in.)

PRESENT.—Messrs. F. Sanders (chair), J. Symons, J. R. G. Thomas, A. Dempster, D. Murphy, M. McCarthy, J. Dempster, J. Breuer, C. Horton, D. Butterick, A. Shrowder, W. Ninnis, T. Ninnis, J. Smith, M. Murphy (Hon. Sec.), and six visitors.

FEEDING AND BREEDING HORSES.—Mr. J. P. Smith read a paper on this subject. The young stock, he said, suffered most when feed was short, with the result that they fell away in condition, became rough in the coat, and very susceptible to disease. The practice of breeding Shires on the so-termed Clydesdales, he thought, would tend to improve the horses. The heavyweight horse, with a good body and capable of moving well, was best. There had been pure-bred Clydesdales in this State, and the foals by these from local mares showed no marked improvement. South Australia did not possess sufficient good horses to warrant the compilation of a Stud Book. Horses registered in such a book should be passed by a board composed of competent judges and two qualified veterinary surgeons. In his opinion the best animals were bred from the common mare. High prices should not be paid for brood mares; the money was better spent in the purchase of a good stallion from one of the other States, where they were bred. When rearing horses it was advisable to breed the best. Mares with foals should not be kept at work too long without the foals being allowed to suck; this frequently caused milk fever. The foals would probably scour, however, if they drank from the mares in a heated condition. Regular feeding was essential. Standing on wet manure was bad for the feet and legs of the foals. Chaff for young foals should be damped and bran added. Farm horses during the summer should receive plenty of chaff and bran and small quantities of oats. The latter should be cut with a binder and stacked. For winter feeding they should receive plenty of good hay chaff, with boiled barley and bran added. Eight hours work per day was quite sufficient. The animals were better watered before they were fed; they were then not so likely to suffer from colic. Well water was preferred. Rock salt should be kept in the manger, and each animal given Epsom salts once a week during the summer. Collars should be kept in good order; when they wore out they should be relined without hair. Backbands and spiders kept the draught in the correct place. He thought the stamp of horses in this district had deteriorated during the last 20 years.

Wirrabara, October 18.

(Average annual rainfall, 18·91in.)

PRESENT.—Messrs. J. Hollitt (chair), E. J. Stevens, E. Kavanagh, W. Marner, S. Thiselton, P. and H. Lawson, W. H. Stevens, E. Hollitt, C. H. Curnow, C. T. H. Borgas, F. T. Jettner, H. Jericho, E. H. Piper, W. Bowman, O. and H. Woodlands, R. Curtiss, E. Pitman, P. R. Hoskins, P. J. Curnow, J. Fitzgerald, and H. R. Woodlands (Hon. Sec.).

COLD STORAGE OF FRUIT AND EGGS.—Mr. H. E. Woodlands read a paper, in which he drew attention to the advantages that would follow the erection of a cool store, on the co-operative principle, in this district. In the event of the market being glutted, which was not at all an infrequent occurrence, growers could store their fruit until such time as prices improved. He mentioned an instance where apples had been purchased at 2s. 6d. per case, stored for 27 weeks at a cost of 2s. 2½d. per case for storage, and sold at 10s. to 12s. per case. The approximate cost of erecting a local store, to hold 5,000 cases, was £1,500. The bulk of the fruit grown in this district was marketed within four months. With cool store accommodation growers could extend their selling season for pears to seven months, and for apples to 12 months. Peaches and apricots, if carefully packed before they were ripe, could be kept for from one to three weeks. Eggs also might be stored when prices were low, and sold when the market had improved. Mr. J. Fitzgerald advocated the co-operative erection of a cool store in the district. Mr. P. J. Curnow thought the district was not yet in a position to do this.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Crystal Brook, October 11.

(Average annual rainfall, 15·62in.)

PRESENT.—Messrs. W. W. Lovelock (chair), H., S., and E. Billinghurst, A. E. Cooke, A. E. S. Clarke, W. S. Carmichael, H. Growden, R. Heaslip, J. H. Hill, W. Jasper,

T. L. Kelly, A. Macdonald, J. Pridham, R. R. Shaw, G. A. Solomon, J. Teakle, W. J. Venning, M. and B. Weston, A. J. L. Wilson, J. B. Greig, C. J. Jenner, G. Gum, A. J. Dennis, A. Munday, F. E. Burgess, and W. W. Robinson (Hon. Sec.)

Pig-Raising.—Mr. Hill read the following paper:—"With good management pig-raising is one of the most profitable lines on the farm. Proper attention and regular and liberal feeding are essential. The farmer should select a convenient spot on a piece of rising land for the stys or pens; the number of these should be according to the number of pigs kept. He should have about 10 acres divided into three paddocks, fenced with netting with barb wire on top and one or two rows of the same about 3in. and 6in. from the bottom, which will keep the pigs from rooting up the netting. These paddocks should have a water frontage, if there is a running stream on the farm, as the pigs do better when they can wallow in water in hot weather. The paddocks should be sown with fodders and fed off alternately, which is a great saving in the cost of feeding. In this district I find barley and rape do well, but where lucerne or root crops can be grown I would prefer laying one paddock down in this for summer feeding when the barley and rape are done. A straw stack should be built in a small paddock, which should enclose the pens and abut on the three grazing paddocks. Dry sows or any surplus pigs do better running out and camping at the stack than penned up. To achieve the best results the pens must be kept thoroughly clean. They should be built of stone, about 9ft. by 8ft. and 6ft. high, well-ventilated, and with a straw roof, as it is much cooler in summer and warmer in winter. Pigs must be kept warm in cold weather or they will not put on flesh. The breeding-pens should have a railing of jarrah about 6in. by 2in. placed about 6in. from the wall and floor so that the sows cannot crush or smother the pigs at the time of farrowing. The floors of the pens should be of brick and well-drained, as the brick is not so cold as flags or concrete. Water should be laid on handy to the pens to save labor. A 200gall. tank with the top cut out makes a good receptacle in which to mix the feed. I strongly advise farmers to think not 'how cheap' but 'how good' when selecting breeding stock. Try to obtain them from a large litter and of a good breeding strain. A great deal of the misfortune in the pig-raising has been due to weedy and mongrel-bred stock to start with, in-breeding, and lack of attention. Cross-breeding may be all right with some, but be sure and have pure breeds on either side. Personally I prefer the pure-bred Berkshire, but when we have customers we must breed to suit their requirements. The sow should be roomy, long, and deep, with broad loins and strong back; she will then have the carrying capacity for her pigs. My experience has been that the long and roomy sow will usually produce more pigs than the short sow. If selecting Berkshires see that the markings are right, and that the ears are set on well, not too large and loppy, and that the nose is not too long. There seems to be a tendency with the Berkshire breeders of to-day to get too much nose on this breed of pig. The boar is the most important member of the herd, as is the sire in the breeding of all stock. He should be a pure-bred animal of the very best type obtainable; well set on his legs and active. Like the sows, he should not be mated too young, but always kept in good condition. A better percentage of pigs and more robust and healthy litters will be secured from a boar in good condition than one thin and weak. If handled carefully and kindly they do not become savage. When rearing stud pigs careful mating is required. Do not let the sow rear too many. Thin out the smallest and those that are not marked too well, and sell nothing but the best for stud purposes. A small yard should be erected so that the young pigs can get under and away from the sows. With a little coaxing the little ones will start to feed on soft feed at about three weeks old; by the time they are eight weeks old they should be fit to wean. They will be feeding well, and will have grown far better than if left entirely to the sow to feed. It is a big mistake to rush into the pig-breeding just when there is a scarcity of pigs in the market, as often by the time one gets to work the market is down. Have the sows and boar always on hand and breed them all the year round; there is always a fair sale for well-bred and well-grown pigs. Sow a few acres of barley on well-cultivated and clean fallow. In an average year this will give a good return. I prefer to grind the barley as fine as possible. Soak it in a tank or barrel supplied for the purpose mixed with the skim milk and slops, &c., from the house. A little wheat headings or grain should be put down for them to pick at; peas also make an ideal feed. If the pig is not worth feeding it is not worth rearing. No animal on the farm will pay so well for its feed. When weaning stud pigs, which should always be put on the market in good order, cattle food is a good thing to use. They thrive well on it, and it puts on a nice glossy coat. Mix it with a little skim milk and pollard. The Berkshire is the most favored pig in Australia; it is a good doer and gives a good amount of lean streaks in the bacon, and is second to none in shape of ham. The meat is sweeter and finer in the grain, and not so coarse and stringy as is the case with some of the other breeds." Mr. Venning thought a great deal depended on cleanliness and the selection of the breeding stock. Inferior wheat could well be disposed of by feeding it to pigs. Mr. Heaslip thought a Berkshire-White Yorkshire cross better than the pure Berkshire. The White Yorkshire was not so oily and developed faster. Mr. Teakle thought the Yorkshire-Berkshire the best cross. Mr. Shaw thought pig-raising was profitable if well carried on. Good feeding, cleanliness, and proper mating were essential. Mr. Dennis considered the Essex the most profitable pig. It grew more quickly than the Berkshire. Refuse from the house made excellent feed; soaked or steamed corn sweetened with pollard was good for topping off. They should be given as much as they would eat for about a fortnight before selling. In reply, Mr. Hill said that while the Yorkshire might grow a little more quickly than the Berkshire, the meat was stringy. The Poland-China carried too much bone. If the sow were given a certain amount of meal at the time of farrowing she would not devour her young. Peas were an excellent forcing food.

Gladstone, October 4.

(Average annual rainfall, 16in.)

Present.—Messrs. R. E. Lines (chair), Henshaw Jackson (wool expert), J. H. Sargent, W. Brayley, T. Mutter, F. Mutter, J. Page, R. Peters, H. Fay, E. H. Davies, S. Masters, J. Coe, R. Coe, J. Fisher, G. Fisher, A. E. Dinning (Hon. Sec.), and 13 visitors.

Sheep.—The Wool Instructor to the School of Mines (Mr. Henshaw Jackson) delivered an interesting address on this subject, dealing in detail with the results of experiments he had been conducting in connection with the hand-feeding of sheep.

Mount Bryan East, October 11.

(Average annual rainfall, 15·81in.)

Present.—Messrs. J. Thomas (chair), R. F. Thomas, L. and B. Weller, W. Hughes, E. Wilks, W. Campbell, H. and F. Trallagar, J. Doyle, (Hon. Sec.), and two visitors.

Pastures.—In a short paper on this subject the Chairman said that during the past year or two feed in the district was becoming thinner and possessed less body than it had formerly. The rainfall had been lighter than usual, and the natural agencies—temperature, wind, &c.—had had the opportunity of restoring the soil to fertility during these somewhat lean years, with the result that better yields would again be secured with a return of the normal rainfall. If the feed became at all short it was advisable to reduce the stock and avoid eating out the grass. It was a good indication that pastures were being properly handled when fat stock could be marketed in or out of season. Some members had found the practice of keeping ewes much more profitable than wethers.

Mundoora, October 22.

(Average annual rainfall, 14·11in.)

Present.—Messrs. W. J. Shearer (chair), C. E. Dalling, C. H. Button, J. Clothier and G. F. Johnson (Hon. Sec.).

Homestead Meeting.—The meeting was held at the homestead of Mr. C E. Dalling. Members inspected the smithy, stables (which consist of 22 stalls), engine-house, cutter, and chaff-house, shearing-sheds, and other items of interest on the farm. Special notice was given a set of stump jump harrows manufactured on the farm, also a contrivance for smoking bacon, consisting of a 400gall. tank connected by a 4in. pipe with a tar drum in which the fire was lighted. A useful draught stallion, very quiet, which was used for general farm work as well as service, was noticed in the stables.

Port Broughton, September 26.

(Average annual rainfall, 14·44in.)

Present.—Messrs. T. Pattingale (chair), G. Pattingale, Routley, W Excell, P. Whittaker, A. J Fletcher, J. H. Fletcher (Hon. Sec.).

Fallowing.—In a paper on this subject, Mr. Excell said he preferred a good strong plough, well set, and not strained for fallowing. If the weeds were not too strong, a skim implement could be used. The land should be worked to a depth of at least 3½in. before the end of August, and within two or three weeks the harrows should be put over it, unless it were wet. It should then be cross-harrowed, and worked about the middle of September; the cultivator being used in preference to the skim plough, as it left the surface rougher. Straw and rubbish were better ploughed in than burnt. The land should lie out for two years before being fallowed. Mr. Allchurch (a visitor) said the great advantage of burying straw was that it tended to prevent drift. He practised deep ploughing, and his neighbor ploughed shallow; in both instances the crops were good. If they could stir the ground to a good depth without causing it to drift it would be of considerable benefit. Three and a half inches was the best depth for ploughing locally. Mr. G. Pattingale thought it better to plough to a depth of 6in. or 7in. on the flats; 3½in. was sufficient in the hills. Regular ploughing to the same depth caused a hard pan to form. The land should be cross-harrowed immediately after ploughing, the stubble being turned under. Mr. Goodridge (Pine Forest) mentioned the case of a farmer who fallowed to a depth of 1in., and worked the land well in September, and secured very good crops. The Chairman recommended harrowing immediately after ploughing. Where there was not too much rubbish the cultivator was more satisfactory than the plough. Members generally agreed that it was best to work the land east and west, and where weeds were not too numerous, the cultivator was the most suitable implement.

Port Broughton, October 10.

(Average annual rainfall, 14·44in.)

Present.—Messrs. T. Pattingale (chair), P. Whittaker, G. Pattingale, Donnelly, Hill, C. Routley, A. J. Fletcher, D. Allchurch, J. H. Fletcher (Hon. Sec.), and one visitor.

Fallowing.—The Hon. Secretary had made a comparison of the crops on land ploughed in March, 1912, July, September, and March, 1913. The first two were sown with Gluyas, and the latter with Gluyas and King's White, 90lbs. of super. per acre being applied. On the autumn and winter ploughed fallow the crops were about equal and very good; that ploughed in the spring would only yield about two-thirds the return of the two mentioned, whilst the land broken up just before seeding would yield only about half. He had come to the conclusion, therefore, that the area left for winter fallowing should be only as much as could be undertaken comfortably, the rest being done in the autumn. Autumn fallowing destroyed the weeds much more effectively than spring or later breaking up. Mr. G. Pattingale stated that Professor Perkins had said that this practice could only be continued for a while. Green manuring would be necessary to maintain the full fertilising and mechanical conditions. One did not allow weeds to grow on the fallow, consequently there was no loss of moisture in this direction. He made a practice of working his land deep in the wet years and shallow in the dry. If, in the latter case, it were worked too deeply, the seed would probably be put in too deep, and possibly a considerable amount of it would malt if the seeding rains were unfavorable. Mr. Donnelly said bacteria were more active in fallow land, consequently it was more fertile. These required a certain amount of moisture to enable them to work freely. When scrub was burned the bacterial action was facilitated and good crops resulted.

Veldt Grass.—Mr. Hill mentioned that a crop of this grass had matured ready to cut for hay seven or eight weeks after the seed was sown. It was very drought resistant, but susceptible to frosts. It needed to be sown annually.

Port Pirie, September 6.

(Average annual rainfall, 13·21in.)

Present.—Messrs. J. Greig (chair), W. Munday, T. Johns, F. Johns, D. L. McEwin, W. R. Wright, and H. M. Lawrie (Hon. Sec.).

Afforestation and Sand Drift.—Mr. W. Munday read a paper. The disastrous effects of drift were, in a large measure, due to the destruction of timber on vast areas of mallee lands, he said. At the present time thousands of acres of promising wheat crops were being covered with drifting sand. Bare fallowing and the practice of burning stubbles was also, in a large measure, responsible for this drifting. The denuding of large areas of timber, he contended, was affecting the climate and rainfall. The problem was a serious one, but was not insurmountable. Continuing, he said—"The State may fairly be asked to assist by inaugurating a vigorous policy of afforestation on Crown lands suitable for the purpose and repurchasing land in settled districts where available, and the locality, soil, and rainfall are of a character to promote the growth of timber suitable for commercial and general purposes. Much might be done if owners of land combined in the planting of trees suitable for shelter purposes along the boundaries of their respective properties, and the division of the various paddocks and corners Also portions of stony or otherwise waste land may be planted with advantage to stock and crops, and I am satisfied will more than compensate for the space taken up. In selecting trees suitable for shelter we must be guided by the character of the soil, locality, rainfall, and general conditions. Amongst the various kinds that may be found suitable, I have found the pepper tree to be one of the easiest and quickest to grow on my farm, and for shelter purposes it is hard to beat. I recognise, however, that it has no value for fencing or general purposes. The sugar gum, while more hard to establish, has the advantage of being useful for many purposes, but unless planted in congenial soil does not grow so rapidly as the pepper tree. Also upon soil suitable the pine is, perhaps, one of the most useful and valuable of our native timbers, giving splendid shade and shelter to stock. There are various kinds of shrubs suitable for hedges, the boxthorn being a rapid grower and fairly easy to establish, but harbors vermin, sparrows, &c. The Government should make it compulsory for every owner of land throughout the State to conserve or plant sufficient timber to meet this need. Help, in the shape of bonuses, towards this end might be given. I feel sure, with the hearty co-operation of the State and the landowners generally, a vigorous policy of tree-planting carried out on these lines will, in the near future, bring about a vast improvement in the direction of preventing the present havoc and loss through deforestation, and will also tend to bring about more favorable climatic conditions in the shape of increased rainfall and less aridity." The writer also thought that the future covenant to purchase land, issued by the Government, should include the reservation of a certain portion of the natural timber or the planting of trees. Mr. McEwin said narrow breakwinds were of little use, as the wind swept along between the breaks, causing the sand to bury fences and bushes. Stubble ploughed in on sandy land tended to bind it together. Mr. Eagle had planted sorghum on sand drifts and found that it grew well and prevented the drift. He advised leaving as much rubbish as possible on the land and not working it down too fine.

Redhill. October 14.

(Average annual rainfall, 16·79in.)

PRESENT.—Messrs. W. Pengilly (chair), D. Steele, F. Wheaton, Kelly, Stone, McAvaney, Potts, Treloar, Lines, Jackson, Larcombe, E. and B. Steele, A. and R. Dick, W. Hayes (Hon. Sec.), and four visitors.

HOMESTEAD MEETING.—The meeting was held at the homestead of Mr. D. Steele. The stables, which were well designed and drained, and the crops were inspected. Members were particularly interested in a seed-grading machine which did good work

DISEASES OF WHEAT.—Mr. J. J. Kelly read a paper on this subject. When the spores of the smut or bunt came in contact with the wheat grain and adhered to it after sowing, he said, they germinated and grew with it, the bunt balls, consisting of spores of the fungus, taking the place of the grain. The spores only germinated when supplied with a sufficiency of moisture, and in the event of their not coming in contact with a young wheat plant on germination they died. Dry-sown wheat was not so likely to be attacked as wet sown ; and some varieties were more susceptible to the disease than others. Oats and barley were affected with loose smut. Bluestone was the best preventive. The grain should be floor pickled a month before sowing and allowed to dry before being rebagged. The cask method was unsatisfactory, as the grain in the centre of the bag was not reached by the pickle. When black rust or flag smut was troublesome it was advisable to work the land at least once in a wet state. Too much rubbish should not be ploughed in. It was always advisable to include some rust-resisting wheat in the sowing. In his opinion takeall was the outcome of successive cropping, too deep ploughing, with insufficient after cultivation, and working the land in a dry state. He advised burning the stubble and keeping the fallows clean of weeds. Rubbish should not be ploughed in. Affected areas should be sown to oats, a suitable rotation being wheat, oats, fallow, etc." Mr. F. A. Wheaton said feeding off crops was a good means of checking takeall. Thorough cultivation was also advisable. Mr. J. A. McAvaney advised sowing oats.

WOOL-CLASSING.—On October 17th the Wool Instructor (Mr. H. Jackson) gave a demonstration of wool-classing before a number of members and visitors.

Spalding, October 17.

(Average annual rainfall, 20·25 in.)

PRESENT.—Messrs. E. E. Gill (chair), P. A. Gill, Walsh, Kelly, Heithersay, Gale, Neill, Marron, C. W. Smith, McAskill, Thorn, Sommerville. Richardson, Wilson, D. A. Campbell (Hon. Sec.), and 22 visitors.

RED WORMS AND HOVEN.—Mr. Rundle gave an address on veterinary matters, in the course of which he spoke on the ravages of the red worm in the district. He advised farmers who were obliged to use surface water for stock, to purify same with sulphate of copper, 10lbs. to 40,000galls. of water. Drinking troughs should be scoured once a week. For a horse that had got at wheat he advised giving a dose of 8ozs. of Epsom salt, 4ozs. of bicarbonate soda, 1 oz. ginger, and two hours after allowing the animal as much water as he cared to drink. Cattle suffering from hoven should have a broom handle placed across the mouth to hold it open, this being secured by straps to the horns on either side. In most cases this was sufficient to give relief.

Whyte-Yarcowie, October 13.

(Average annual rainfall, 13·91in.)

PRESENT.—Messrs. G. F. Jenkins (chair), Robinson, McGregor, J. R., G. W., and W. Mudge, Wittwer, E. F. Pearce, Van Senden, E. J. Pearce (Hon. Sec.), and eight visitors.

WOOL-CLASSING.—The meeting was held at the residence of Mr. E. M. Jenkins, and a demonstration of wool-classing was given by the Wool Instructor of the School of Mines (Mr. H. Jackson).

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Clare, September 12.

(Average annual rainfall, 24·30in.)

PRESENT.—Messrs. J. Scales (acting-chairman), I. C. Radford, H. Hanna, F. J. Gertau, F. Knappstein, C. Radford, W. J. Maynard, M. L. Nolan, A. Hill, F. G. Hicks, C. T. Jarman, F. Pink, R. Hunter, C. Pink, and P. H. Knappstein (Hon. Sec).

FRUIT-GROWING.—Mr. F. J. Gertau read a paper, in which he recommended for planting in this district a few acres of currants, prunes, and pears for drying and export, export apples, peaches, apricots, and sultanas. This would provide employment in the orchard all the year round; and in the event of one crop failing, a total failure of income would not result. There was also a greater likelihood of a demand arising in England for such dried fruits as pears, prunes, peaches, and apricots. Peaches, apricots, and sultanas should be put in on the red limestone ground, prunes on the flats in deep black soil, and currants on slightly higher ground where they would escape frosts. The land should be fallowed and subsoiled if possible. Good trees and vines for planting were essential. Mr. Hicks did not think it would pay to grow peaches in this district. Mr. C. Radford said that peaches grown in suitable soil were very payable, and gave an instance of an orchardist in the district who netted £44 from half an acre of these trees. Mr. Hunter said peaches were payable. Prunes should do well here on the rich flats. Currants were pretty well exhausted, but had not reached the limit yet, owing to the increasing consumption of the last few years. It was not advisable to subsoil all classes of soil as mentioned in the paper, as in some cases the clay was close to the surface, and it would not do to turn that up to the top. Mr Jarman advised anyone thinking of planting to fence the land well with wire netting to keep out hares and rabbits, as they would destroy the young trees. He was unfortunate in planting early peaches. He preferred apricots, as they came in earlier than currants and the grower had time to get them dried and finished with before the busy season came on. Prunes might be overdone. He believed in ploughing the soil as deep as possible, and then following along in the same furrow with a plough that had the mouldboard taken off, which did not turn the clay up to the surface, but only just loosened it. Mr. I. C. Radford had apricot trees which were 20 years old, and from the time they came into bearing at five years old up to the present he had only had one failure with them. They were planted on limestone soil with an easterly aspect. The amount of prunes consumed was enormous, and he did not think they could be overdone, so growers need not be afraid to plant them Jam made from dried apricots was preferable, he thought, to jam made from the fresh fruit. Mr. P. H. Knappstein congratulated the writer on his paper, and agreed with his views in the main. He thought that apples did not pay to grow. Duchess pears, wine grapes, and sultanas were the most profitable varieties at the present time, as well as a few good prunes on good deep and damp alluvial soil. There was a great future for wine grapes. Members considered that it was time to start grafting when the buds were just starting to burst. Mr. P. H. Knappstein said it was a difficult matter for a man who canned his own fruit only to find a market for the product. If a co-operative cider factory were started in this district it would prove a paying concern, as there was a ready market for cider.

Freeling, September 29.

(Average annual rainfall, 17·85in.)

PRESENT.—Messrs. A. J. Kuhlman, G. T. Elix, C. A. Schultz, F. W. Schuster, E. Savage, J. H. Gramp, E. Morris, A. Elix, M. Shanahan, J. E. Veldner, H. Neindorf, H. Koch, C. H. Mattiske, F. W. Schafer, C. W. H. Koch, J. Wegner, E. C. Leske, A Heinrich (Hon. Sec.), and two visitors.

SCIENTIFIC FARMING.—In a paper under the title "What is Scientific Farming," Mr. G. Boerke read an interesting paper, in which he said—"Measurement is the basis of all the sciences, and therefore of scientific farming as well. Consider the case of two dairy farmers, for example. The first keeps a number of cows, cares for them to the best of his ability, and sells his milk to the creamery, cheese factory, or to the city. The second keeps the same number of cows, cares for them equally well and sells his milk in the same way, but in addition he measures the milk given by each cow, by weighing it at each milking. He measures the food given and the labor used, so that at the end of the season he knows exactly the profit from each cow, or whether some of them have been a loss to him. He knows which cows are yielding a profit, and to what extent; also which cows, if any, are living at his expense. We shall all agree that the second farmer is the more scientific of the two. Again, science teaches that warmth in the animal economy is produced and maintained at the expense of food consumption. Every practical farmer knows that keeping cows warm by rugging them means a saving of food and an increase in the production of milk. This has been proved by Mr. O'Callaghan, Dairy Expert, New South Wales. He states in a test taken during an eight weeks' spell of wet and frosty weather unrugged cows fell off 31 per cent. in their milk, while the cows which were rugged at night only fell off 18 per cent. in their milk; also, that if cows were rugged day and night through bleak cold weather there would only be a loss of 5 per cent., or, compared with cows not rugged, a gain of 26 per cent. In growing field crops the scientific farmer will measure the size of each field, the amount of grain planted, the amount of labor expended on each crop, and at the end of the season the amount of the harvest in grain and straw Thus he is in a position to know exactly the profit obtained from each crop. Measurement then is the first step in scientific farming. The second is to keep an orderly record in which the measurements for each cow and each field, &c., are entered when made. These records give the scientific farmer an exact knowledge of the results he is obtaining from his farm, and this exact knowledge is the starting point in the search for improvement. In looking for improved methods the scientific farmer compares his own methods and results with those of successful farmers in his locality and in all parts of the country. He studies the methods used and the results obtained along his line by the experts of the Government and of the Agricultural Colleges. He tries to learn *why* these methods give the results they do, so that he may be in a position to judge of their applicability to his own case. If, as a result of this study, he decides to try certain new methods to see if they will produce improved results, he does not apply them to his whole farm, or whole herd, but to one field or to one or two cows; that is, he makes an experiment, and he is careful to measure every factor in the experiment that has a bearing on the result. If the experiment shows that the new method gives increased results he applies it to his whole farm or herd, keeping up his measuring and recording of measurements to see what the results are on a large scale. These new measurements are then studied for further improvement. The value of experimental work is being recognised more and more by leading agriculturists. Experiments that require a special knowledge of chemistry or biology cannot easily be carried out by ordinary farmers, but there are many experiments that are well within the power of every practical farmer, such as seed tests, graded or otherwise; quantity of seed, small or cracked grain and specially selected grain; sowing catch crops; which is the most profitable sheep for farm conditions; depth of sowing; pickling wheat, with bluestone, fungusine, formalin, or hot water treatment; manure tests, as to quantity and variety on experimental manure plots. It is so easy to waste money on chemical manures that the first thing necessary is to think about the matter. To put pounds worth of fertilisers into the land should not be the objective, but to spend the money to the very best and most profitable advantage. There is plenty of literature on the subject—enough to confuse one, in fact. Every firm of manure merchants supplies full directions for using its particular brand of manure, and every State Agricultural Department and experimental station issues numerous reports on the subject. The more one reads the more complex the problem may well appear to be. After mastering the elementary fact that no plant life is possible unless the soil is sufficiently rich in nitrogen, phosphoric acid, and potash, the inquirer is confronted with the difficulty that the amounts of these requirements and the proportion they should bear to each other vary as greatly as do the soils in different localities, and the kind of crops which are grown in them. Multiply the number of classes of soil by the number of different crops grown and the total will represent the number of different manure mixtures that it is possible to use. One may be excused for fearing that he will never hit upon the right thing; and yet, in the absence of a sufficient supply of natural manures, the constituents lacking must be supplied by means of chemicals. No treatise on the subject can inform one *exactly* what kind and what quantity of fertiliser the soil requires—this must be found out by experiment. The first axiom in manuring is that we must return to the soil an equivalent for that which we take out of it; and the chemists can help us here, for analysis will give the exact quantities of the different elements which a crop contains. The basis of the experiments must be the use of a complete manure, that is, one containing the same or greater amounts of nitrogen, phosphoric acid, and potash which a ton of hay or wheat, for instance, will remove from a given area of land. Let the experimental manure plots be at least half an acre in size. On plot 1 use a complete manure, *i.e.*, one that contains nitrogen, phosphoric acid, and potash. This plot may give good results. On plot 2 omit nitrogen. If equally good results are obtained as from plot 1 it will show that money spent on nitrogenous manures is therefore thrown away. On plot 3 omit phosphoric acid, but use nitrogen. On plot 4 omit the potash only. So that there shall be no mistake leave an unmanured plot to separate each of the others. The result of these experiments, if properly measured and recorded, will tell the farmer more than a ton of literature would. This one series of plots will not give all the information required. In another set of experiments the amount of manure used should be increased to see whether it will pay to put more on. In some cases there is a certain maximum requirement, and anything above that produces no increased results; it is waste in the case of nitrogen, but phosphoric acid will remain in the soil as a permanent enrichment. The experiments may further be varied by using nitrate of soda or sulphate of ammonia to supply nitrogen, Thomas' phosphate or superphosphate to supply phosphoric acid, and sulphate of potash or muriate of potash to supply the required potash, and by applying them to the soil at different times of the season.

Friedrichswalde, September 13.

(Average annual rainfall, 18in. to 19in.)

PRESENT.—Messrs. R. Marlowe (chair), F. and J. Heintze, G. Grope, F. W. Duldig, P. Goodfellow, F. W Schutz, T. Pfitzner, R. Zema, J. B. Coombe, (Hon Sec.) and five visitors.

FERTILISERS.—In a paper on this subject the Hon. Secretary said that before fertilisers were popularly used the average wheat yield of South Australia varied from 4bush. to 7bush. per acre, whilst at the present time it was between 9bush. and 12bush. Better methods of cultivation and good seasons had contributed largely to this increase, but the use of fertilisers was mainly responsible for it. Analyses had shown that South Australian soils were deficient in nitrogen, potassium, and calcium to a small extent, but to a far greater degree lacking in phosphorous. A complete manure would return these essentials to plant growth to the soil. Wheat manure, as it was called, seemed to meet the case. It contained a large percentage of soluble phosphate, small quantities of nitrogen, potassium ,and calcium. An increased yield of 1bush. per acre would pay for the extra cost of this manure over superphosphate. The correct quantity to apply could only be determined by experiment. Experiments had been conducted with the idea of determining the value of nitrate of soda and sulphate of potash as manurial dressings, but as these two fertilisers were so expensive a considerable increase in yield was necessary to recoup the outlay. Another disadvantage was that any residue not utilised by the growing crop was lost. With superphosphate this was not the case, as the phosphate became incorporated in the soil as acid soluble. If the farmer, by applying 37lbs. extra of super. per acre, increased his yield by only half a bushel it would pay him to do so. The scope for experimental work in the matter of the quantities of manure to apply, the varieties of seeds to sow, and the quantities to sow was exceedingly great.

Gawler River, October 10.

(Average annual rainfall, 17in. to 18in.)

PRESENT.—Messrs. F. Bray (chair), J. Hillier, G. Higgins, P. T. Hill, C. Leak, W. Richter, E. Winckel, B. F. Hillier (Hon. Sec.), and three visitors.

MARKETING WHEAT.—Mr. E. H. Coombe gave a very interesting and instructive address on the marketing and handling of wheat. He had acted as Chairman of the Wheat Commission, and gave a lengthy account of their work and findings. On account of less competition in this State prices were lower than they should be. There should be some system of storage so that farmers could command their wheat at any time, because if stored with the buyer they were reducing competition. He described the silo scheme of Mr. F. H. Webb, and advised its adoption. These silos could be erected at the Outer Harbor and at places inland by the Government. The farmer, on sending his wheat there, would receive a certificate and could trade with it wherever he liked. This system of storage would greatly reduce the present waste. The wheat could be graded and could be exported either in bags or bulk. The interest on the capital cost would be nothing compared with the advantages derived.

Nantawarra, October 9.

(Average annual rainfall, 15·90in.)

PRESENT.—Messrs. T. Dixon (chair), W. Smith, F. J. Sutton, A. F. Herbert, J H. Nicholls, W. Greenshields, J. Sinclair, and G. L. Tucker (Hon Sec.).

BREEDING AND FEEDING FARM STOCK.—Mr. W. Greenshields read a paper in which he said it would pay every farmer who bred from six or more mares to keep a stallion. When a travelling horse was availed of there was not only the cost of service, but during the season seven or eight days' time was wasted in connection with the service. The animal purchased should be well-bred. Continuing, the paper read—"I suggest a short, nuggety animal, well-ribbed, with plenty of muscle, good flat bones, a fair quantity of hair, and a small head if possible, as a horse with a small head generally takes the eye. It would not pay farmers to buy mares especially for breeding. The medium draught is the most suitable for farmwork, requiring less food than the heavy, and is generally found in the lead. A great deal depends on their treatment when they are foals. When weaning foals it is advisable to shut them up in a place of which they will not be constantly trying to get out. Feed them on good rich food. Dampen the chaff and add bran and pollard; feed often, but only in small quantities so that it will not get sour. If a foal is well looked after he will be ready to break in when two years of age, but if it is allowed to become poor at the start it will most likely have to be fed until three years of age before being fit to be broken in, and even then it will not make the horse it otherwise would. We can make our haystacks last a great deal longer if we use more corn. I favor oats, as they do not cause boils, but give the animals strength and plenty of life. It is a good plan to have a big stable yard with a stack of straw in it. When a horse wants to rub himself he will do so on the straw. He is thus able to rub off the sweat and keep himself much cleaner, and consequently save time in grooming. Boxes containing salt should be kept about the yard so that the horses may easily help themselves when they need it." Mr. A. F. Herbert agreed with the writer of the paper, that it paid to keep a stallion. He advocated getting a young one and making a worker of him. While medium draught horses did as much work as the heavier type it was better to breed the heavy class, as their market value was greater. Mr. Sutton said the choice of a stallion was ruled by the condition of the buyer's pocket. He favored a nuggety horse, but concurred with Mr. Herbert that the selling value of the heavy draught was greater than that of the medium. He advised care when feeding grain to farm stock. Mr. Sleep considered six mares too small a number for which to keep a stallion. He agreed with the paper in regard to stamp of horse for farm purposes. It did not pay farmers to breed for market. Mr. Smith thought attention should be paid to the class ot mare bred from. The breeding of a right class would prove profitable to farmers. When a stallion was kept the mares could be caught in season. Mr. J. H. Nicholls thought it would not pay to keep a stallion for only six mares. If a stallion were kept it should be a good one, and the farmer did not care to incur the risk of injuring a valuable stallion by working it. Little time was saved in service through a farmer owning the stallion. He agreed with the paper in regard to the type of horse for general farm use It would be better to put a straw stack in the paddock for the horses to rub on; thus doing away with the attendant litter. In reply, Mr. Greenshields did not consider having to keep a stallion in his stall a disadvantage. There was always a horse ready to hand when wanted, and consequently the stallion did more work than any other horse on the farm.

Riverton, July 26.

(Average annual rainfall, 20·48in.)

PRESENT.—Messrs J. P. Schultz (chair), W. Legoe, R. H. Cooper, R. Wilkinson, T. Camac, J. W. Kelly, W. B. Davis, W. Stacey, F. Phillips, A. Hannaford, and E. A. Gray (Hon. Sec.).

ODDS AND ENDS ON THE FARM.—Mr. A. Hannaford read a paper under this heading, in which he urged the members to prevent waste on the farm. Scraps of iron, &c., which were frequently thrown about could be utilised for bolts, repairing implements, &c. Regular inspection of fences was advisable, and considerable time and trouble would be saved by putting in serviceable gates in place of makeshifts. Attention should be paid to horses' mouths, particularly to see that they were not suffering from the effects of grass seeds, and that their teeth were in good condition. Harness should be hung up and oiled periodically. The use of wax and thread frequently made a much better job of small repairs than tying with wire or string. Implements should be kept in good repair, the woodwork being painted to protect it from the weather. Cows, pigs, and poultry, to supply the needs of the household, would be found valuable.

Salisbury, September 9.

(Average annual rainfall, 18·57in.)

PRESENT.—Messrs. Moss (chair), Tate, Frost, Bussenschutt, James, Hooper, Bagster, Short, Ray, Fleet, Illmann, Eyre, Jenkins, and seven visitors.

THE AGRICULTURAL BUREAU.—A paper on "The Agricultural Bureau, and a few of the reasons why farmers should support it," was contributed by Mr. S. Eyre, of the Georgetown Branch. The writer was quite satisfied that it would pay every farmer to become an active member of this organization. Practical farming was becoming more and more a science, and the man who was contented to jog along in the old narrow way was soon left behind by his progressive neighbour. The Bureau was to the farmer what the public school system was to the child. The idea of Branches possessing a bound volume of the *Journal of Agriculture* was a good one. The spirit of emulation engendered by the holding of homestead meetings had much in its favor. A great deal of the success of a Branch rested with the Hon. Secretary and the Chairman. Regularity of attendance was essential. Closer attention to the rules of debate during discussions would in some cases be an improvement. General conversation during discussions should be checked.

Salisbury, October 2.

(Average annual rainfall, 18·57in.)

PRESENT.—Messrs. Moss (chair), McNicol, E. V. and H. J Harvey, Tate, Frost, Neal, Judd, Hooper, Bagster, Baylis, Ray, Fleet, and Wilkinson.

NITROGENOUS MANURES.—A paper on this subject was read by Mr. Crawford. The writer of the paper emphasized the importance of the addition of nitrogen in some form to land carrying cereal crops. If the soil were deficient in any one of the essential elements of plant food, he said, the crop would be affected, and a superabundance of other plant foods would in no way compensate for the absence of this one. The relative values of different forms of nitrogenous manures were discussed. Members agreed that it was advisable to thoroughly test the effect of applications of nitrogenous fertilisers. [A reference to page 1097 of the May, 1913, issue will show the result of eight years' tests in this connection, conducted by Mr. F. Coleman, of Saddleworth.]

Stockport, October 10.

(Average annual rainfall, 15·89in.)

PRESENT.—Messrs. D. G Stribling (chair), F. Watts, T. Megaw, E. Weckert, C. W. Cant, T, Howard, S. Nairn, G. Thomas, C. Perry, R. Whitelaw, and J. Murray (Hon. Sec.).

TWENTY-FIRST ANNIVERSARY.—The Hon. Secretary reported that a very successful gathering had taken place on the 19th August in connection with the twenty-first anniversary of the Branch. Addresses were delivered by Messrs. Gordon, Coleman, and Kelly, of Saddleworth Branch; N. S Kelly and J. Nairn, of Mallala; and in the evening the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) and Mr. G. R. Laffer (Chairman of the Advisory Board).

COMPARISON OF SEASONS.—It was decided that a record of the results of the harvest during successive years on a particular section in the district should be kept in the minute-book of the Branch

Two Wells, September 16.

(Average annual rainfall, 16·36in.)

PRESENT.—Messrs. E. H. Green, J. W Hart, J. Williams, R. Kenner, H. W. Kenner, A. Pratt, H Goss (Hon. Sec.), and one visitor.

FARM HORSES.—In a paper on this subject, Mr. H W. Kenner said the best horse for the farm was the thick-set, medium draught. This was easily kept in condition, was a good mover, capable of drawing heavy loads. The stallion selected for breeding should be active and sound and have the Government certificate. The Suffolk Punch was a good horse to mate with a heavy mare. Mares of this breed should not be used for breeding until they were 4 years old. An animal that kept fat when in foal should be worked to within a few days of the time of foaling. After foaling the animals should be fed from a low manger, in order that the foal might be encouraged to feed. It should be given plenty, and allowed about the stable with the other horses. The first item of its education should be mouthing. Light work should be given at the age of 2½ years. Stables should be of stone and iron, and cleaned out every morning. Grooming should be carried out thoroughly, and when an animal was suffering from sore shoulders it was advisable to cut the collar and so ease the trouble. A galvanized iron trough should be provided in the stable yard, the horses being watered before and after being stabled and fed. All chaff was the best feed, unless good short feeding hay could be grown. Salt should be kept in the mangers, especially if Barossa water were used. Mr. Pratt thought it unwise to have a trough in the stable yard.

Watervale, September 15.

(Average annual rainfall, 27·17in.)

PRESENT.—Messrs. E. E. Sobels (chair), W. Smith, F. Burgess, A. Burgess, F. L. Burgess, A. Davis, F. Hunter, O. Dunstan, G. Hunter, J. Scovell, J. Broadbent, W. Tavender, C. W. Grace, F. Hamp, J. R. Hamp (Hon. Sec.), and one visitor.

PEACH TREES SHEDDING BUDS.—Mr O. Ward, in a paper on this subject, said that Briggs May and Hales Early varieties of peaches, which were two of the first to be ready for market, frequently gave a large show of buds. The majority of these, however, failed to hold as the season advanced, with the result that should the trees have been pruned n the ordinary way the crop would be very light. He found these varieties profitable to grow, but made a rule of pruning them just when they were coming into bloom. He was thus enabled to form an idea of the crop that would be carried, and the pruning could be adjusted to the conditions. If, as occasionally happened, the trees came through the late winter without shedding many of their fruit buds, the crop could be easily thinned. In discussing the subject, Mr. F. Burgess preferred to prune the Briggs May varieties early, as he thought the peaches then filled out better. Mr. Holder believed in pruning the peach trees just as the buds were about to burst. One was then able to see which wood it was best to leave. Mr. Hunter was troubled with sparrows picking the peach buds when the trees were blooming.

Watervale, October 13.

(Average annual rainfall, 27·17in.)

PRESENT.—Messrs. E. E. Sobels (chair), J L. Broadbent, O. Ward, J. Scovell, W. Tavender, A. Burgess, F. L. Burgess, W. Baker, A. Davis, and J. R. Hamp (Hon. Sec.).

STRAWBERRIES.—In reply to a question, Mr. Broadbent advised allowing strawberries to fruit during the first year, runners for fresh plants should then be planted. The best time for planting was in the winter months, the plants being put in rows and left until they grew into a mass. They should then be rooted out and put in again. A heavy manuring was advisable. Mr. Burgess mentioned that when allowed to grow in a mass, as recommended, there was a difficulty in keeping the strawberries free of weeds,

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Maitland, October 4.

(Average annual rainfall, 20·08in.)

Present.—Messrs. Smith (chair), Bawden, Bentley, Darling, Hill, E. G. and A. Jarrett, Tossell, Wundersitz, Pitcher (Hon. Sec.)

Water Conservation.—Mr. Bawden read a paper on this subject, in which he stated that the present season had shown many farmers the folly of depending solely on dams and reservoirs for water for stock. He advised the construction of underground cement tanks, about 20ft. square and 12ft. deep with iron roofs, on different parts of the farm. In his opinion every farmer should construct enough tanks to provide for the whole farm for at least six months. These should be built to about 3ft. above the surface of the ground, and cement troughs should be placed at the sides. A small windmill might be purchased and transferred from tank to tank as each was emptied. The farmers who constructed four of these tanks on every 500 acres would never, in the driest of seasons, be without sufficient water for the stock. They would hold about 30,000galls. each, and cost about £80 Mr. Hill agreed that tanks should be kept full, as a reserve supply when the rainfall was light and scanty. Mr. Jarrett advocated large dams where there was a sufficient catchment.

Fodder Crops.—Mr. Hill tabled a sample of well-grown barley sown in June, and also a sample of self-sown barley and native clover, a good mixture for ensilage, and a particularly well-grown sample of ordinary field peas sown on the 25th July. It was grown on land that produced a good crop of oats last year. He advocated growing peas and feeding them off with sheep until the natural herbage obtained a start and then ploughing in the peas for the benefit of the land. There was too much bare fallow in this district. Mr. Tossell tried peas on fallow last year, but they were unsatisfactory. Sheep would not touch them. The wheat crop was not so good on the land where the peas were grown last year. He attributed that to the peas taking most of the moisture out of the land. Mr. Jarrett, who had been travelling in the South-East, had noticed that peas were grown very extensively near Bordertown. Mr. Hill, in reply, said every farmer should experiment with various fodders on fallow land, and that the land the fodder was grown on should be fallowed again the following year.

WESTERN DISTRICT.

Butler, October 6.

(Average annual rainfall, 16·61in.)

Present.—Messrs. R. W. Phillis (chair), F. Durstan, A. J. Hughes, J. Owen, G. J Parker, C. F. Jericho, D. B. Butler, G. Unvoius, J. G. S. Morgan, S. M. Bawden, J. C. Humphrys, G. Young (Hon Sec.), and four visitors.

House-Building —In an address on this subject Mr. Jericho demonstrated by means of a blackboard the best methods of obtaining levels and of squaring a building. All timber should be cut to the correct measure before the erection was commenced. He mentioned a simple method of ascertaining whether a building was being erected on the square, *i.e.*, 8ft. of the length should be measured from a corner post and 6ft. of the width from the same post. If the shortest distance between these points were 10ft. the building would be found to be square. He would put 4in x 2in. battens on the edge of the roof to strengthen it against sagging, and would give it a pitch of not less than 1in. in 2ft., so the dew could run off and the iron would not rust. The guttering should have a pitch of 6in. in 50ft. ; 24-gauge iron would be found the cheapest in the long run, and it would strengthen the building considerably. Members considered this information very useful, especially to one or two members who were about to erect buildings.

Coorabie, September 18.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. C. T. Giles (chair), W. Cousins, V. R. Weston, F. Woodforde, C. A. Fox, B. Giles, A. Riddle, G. Riddle, W. G. Wheadon, F. M. Underwood, R. Muegge, G. Cabri, H. V. Hobbs (Hon. Sec.), and five visitors,

Farmers' Mistakes.—One of the members read a few notes on this subject, which included putting up makeshift fences, placing wire netting on the fence too far into the ground, want of care in the selection of clean seed wheat, and failure to erect substantial galvanized iron sheds for implements, &c. Several members agreed that it was necessary to put up substantial fences from the first, and emphasised the importance of netting the fences in this district, whether rabbits appeared numerous or not. Several other members then recounted operations they had conducted on their farms, which in the light of experience they had found to be mistakes. They were as follows:—The insufficient working of land and not waiting for rain to fall to re-plough grassy land before seeding. Land sown dry had yielded 6bush. per acre, while similar land alongside worked after rain had yielded 15bush. per acre. Seeding new black grass land, which should first have had the benefit of one year as fallow. Attempting to crop too much land during the first few years. Fallowing, with more thorough working of the land, water conservation, and other matters should receive early attention on a new scrub farm, instead of the farmer merely struggling after a big average of crop. Cultivating scrub land the second year instead of ploughing it. Whether ploughed the first year or not scrub land should be ploughed the second year; otherwise fire bush and other weeds gained a very strong hold. Reaping a dirty crop and then going straight on to new or clean land with the machine. If the crop on new land could not be harvested first, then too much care could not be taken in cleaning out the machines. Continuing seeding into the month of June. Seeding in this district should be finished by the end of May. A week's seeding at the end of April is better than a week early in June. Not cutting the mallee shoots on new scrub land prior to stripping the crop. All new land should be gone over and the shoots cut before harvest. Failure to construct underground tanks for the conservation of water, and consequently having to cart water. The relating of these mistakes gave rise to an interesting discussion.

Elbow Hill, October 11.

(Average annual rainfall, 11in. to 12in.)

Present.—Messrs. Cooper (chair), A. Chilman, H. and S. Wheeler, S. V. Wake, C. E. Jacobs, J. Spence, A. Ramsey, J. F Brooks, G. W.Bradley, F. Freeth, G. F. Wake (Hon. Sec.), and three visitors.

Harvesters v. Strippers.—The relative advantages of the use of harvesters or strippers were discussed by members. Mr. A. Chilman said that the harvester could be started in the crop on an average three hours earlier than the stripper, and could be worked later at night. The wheat was stripped and cleaned in the one operation, and, if so desired, the chaff could be saved by means of attaching a chaff-carrier to the machine. Mr. G. Wake quoted figures to show that the harvester was cheaper than the stripper to use. Also, more grain was lost by the stripper and winnower. Chaffed straw was more nutritious than wheaten chaff. The distribution of weed seeds was advantageous in that it enabled the land to carry more sheep. Mr. A. Ramsey said more grain was secured by the harvester, which he had frequently seen drawn by four horses. Mr. G. C. Dunn contributed a paper, in which he quoted figures to show that the harvester was a money and labor saving machine. Mr W. T Cooper thought the stripper would last much longer than the harvester, which was of very heavy draught, and scattered weed seeds over the land, in addition to wasting wheat. Cocky chaff was very useful in times of draught Mr. Wheeler thought the use of the stripper the cheaper method of harvesting. Mr. S. Wake concurred, and thought there was less wear and tear with these machines. Mr. C. E. Jacobs said that as wheat could be cleaned for 4d. per bag the use of the stripper was advisable.

Mitchell, October 4.

Present.—Messrs. A. E. Howell (chair), W. Sampson, S. Baker, D. Sampson, E. Dyke M. McCormack, J. P. and O. Green, G. Jericho, H. Voumard, D. Ness, G. Wright, R. Merchant, W. Ness, A. Ashman (Hon. Sec.), and five visitors.

Fallowing.—Messrs. E. Dyke and S. Baker read papers on this subject. The best time to fallow, it was contended, was as soon after seeding as possible. Care should be taken in the selection of the plough. If the team tired it was better to take a furrow off and do less than to pull the plough out slightly. The soil should be turned over and exposed to the air, all grass and rubbish being turned over at the same time. The depth of ploughing should be about 4in. The cultivator should be used after the plough, during

September, and after each rain. The land worked much better when wet. Sand that was liable to drift should be worked with discretion.

The writer of the other paper advised fallowing in July and August. In wetter seasons the work could be kept on until October. Very early fallow had a tendency to dry hard, and it should, therefore, be worked as soon as it began to set. All fallow should be lightly cultivated or harrowed with heavy harrows weighted with logs once during the spring, towards the latter end of October being the best time in the average season. The disc cultivator destroyed shoots. The greater part of the land in the district would be better if ploughed to a depth of 6in. ; some of it could be ploughed to even 9in. or 10in. with advantage. The disc plough was very useful where there were shoots and undergrowth to contend with.

Utera Plains, October 11.

(Average annual rainfall, 12.06in.)

PRESENT.—Messrs. Guidera (chair), Rule, Venning, J. and M. Abrook, G. Barber, G. Hornhardt, Gale, Stephens, W. Lee, sen., and J. A. Ramsey (Hon. Sec.).

CONSERVATION OF PLANT FOOD.—Mr. J. C. Norton read the following paper :—" In this and similar districts, where the soil is not particularly rich, it is necessary to husband the supply of available plant food in every possible way. Plants require some nine or 10 different substances from the soil, the chief being phosphoric acid, potash, and nitrogen. These must all be present in a form which is soluble in water, for the roots cannot directly absorb solid matter as food. The presence of humus is of great importance to plant growth, especially in light soils. Humus is formed by the decomposition of vegetable matter, and improves the soil in many ways. Being spongy in its nature it absorbs and retains moisture, and in so doing helps to keep the soil cool and moist in hot weather. It discourages the leaching of manures in sandy soils, and also acts as a cement, holding the particles together. It is the principal nitrogenous ingredient, and to its presence is largely due the fertility of new land. It is formed in uncultivated soils by the decay of the wild plants which have grown on them, and at present we are utilising this accumulated store in growing our crops. It must be our object to return as much of this humus to the soil after we have used it in growing our crop, in order to keep up the supply for succeeding crops. At present by burning our stubble we are destroying the humus, and all the nitrogen, which is contained in it. Of course on new mallee land for the first few years we must burn the stubble to kill the mallee stumps, but it is not advisable to continue this practice longer than is necessary, or we shall exhaust the soil. If we feed down the stubble and plough it in we return all the humus and nitrogenous matter to the soil, except that which has been taken away in the form of grain, wool, or meat. Different plants require different proportions of the various foods from the soil, and when the same kind of crop has been grown continuously on the land and harvested and taken away from it, the soil becomes poor in the chief substances which the particular plant requires as food, unless steps have been taken to replace them, so that land would in time become infertile for that crop Nevertheless it might still be very fertile for another kind of crop which requires other foods in greater proportion. Some plants by their own growth bring into the soil from outside sources materials which will act as fertilisers for other crops. Leguminous crops (*e.g.*, peas, lucerne, clover, &c.) secrete nitrogen, so that when they die and the roots decay they leave it in the ground in a form which is suitable for a food for succeeding crops. Up to the present very little has been done in this locality in the way of any system of rotation of crops, chiefly because the land has been comparatively recently cleared, and has had a good store of the necessary plant foods, but now that the land has grown a number of crops almost entirely of wheat we must look ahead to keep our land in good heart. It is not sufficient to continuously apply superphosphates only as the fertilizing agent, as that only supplies phosphoric acid, which, though the chief one, is not the only food required by cereals. By growing different crops in rotation we make nature supply most of the other foods required instead of supplying them in the form of artificial manures. The following are some advantages of growing crops in rotation, given by the late Mr. J. L. Thompson, late Travelling Instructor of Agriculture in N.S.W. :—It is more economical of manure ; it is more economical of food in the soil ; it allows of a better distribution of labor on the farm throughout the year ; a rotation of deep-rooted or air-feeding crops enriches the top soil for the benefit of shallow-rooted varieties to follow ; some crops are a good preparation for others, such as clover before wheat, &c. ; rotation checks the devastations of insects and fungi, by changing the locality of the crops which they affect ; a system of rotation changes the locality of livestock every year. The growing of forage crops for feeding off on the land and so converting them into marketable wool and meat is an important item in every system of rotation. At present lack of water is a great obstacle to successful stock raising here, but it must be overcome before we can obtain full value from our land. Before adopting any definite system of rotation we must begin by experimenting with various kinds of crops to find out which are the most suitable for this district, and which are the most beneficial for succeeding crops. This is where the Agricutural Bureau branches might show their utility, and make their meetings much more interesting, by organising among their members some original work like this. Various members could be appointed to experiment with certain crops, and then at the end of the season compare the results at the meetings."

Yadnarie, October 11.

(Average annual rainfall, 14.09 inches.)

PRESENT.—Messrs. F. W. Dreckow (chair), W. L. Brown, J. H. Kruger, G. H. Dreckow, E. C. Dreckow, E. C. Kruger, A. Spriggs, R. H. Parbs, B. B. Crosby, S. H. Pearce, J Kruger, P. Briess, A. A. Jericho (Hon. Sec.), and a number of visitors.

HANDLING WHEAT IN BULK.—In a paper on this subject Mr. R. H. Parbs said the general objection to the bulk handling of wheat was the cost of erecting sheds, and weighing machines, and altering the bodies of railway trucks. The money spent in the purchase of bags, however, more than counter-balanced this. These cost 7d. each, and were sold as wheat for 2½d., a direct loss of £20 on every 1,000 bags. A store capable of holding 60,000bush. could be put up for £800, and a weighing machine, with a capacity of 20 tons, would cost £100. With a weighing charge of 3d. per ton, and storage at 1d. per bushel, the cost of handling to the farmer of 60,000 bush. would be £272 10s. Bags to carry this quantity would cost £400, therefore bulk handling would result in a saving of £127 10s. He urged members to use every endeavour to forward the adoption of this system. Members were divided in opinion as to the wisdom of the proposed alteration.

Yallunda, September 13.

(Average annual rainfall, 18in. to 19in.)

PRESENT.—Messrs. F. Olsten (chair), R. B. Jenkins, G. Provis, P. V. Provis, W. and H. P. Cabot, S. C. Fairbrother, T. Allen, W. Winstanley, W. Forrest, G. Teagle, M. Hissey, J. S. Perry, A. G. Price (Hon. Sec.), and two visitors.

MANURES.—Mr. R. B. Jenkins was of opinion that bonedust was the most suitable manure for use in this district. Mr. G. Provis had received good results from fairly heavy dressings of lime applied two or three weeks before seeding. Mr. G. Teagle strongly advocated green manuring with field peas. Messrs. Fairbrother and H. T. Cabot advocated heavier dressings of super. both to wheat crops and pastures.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Berri, August 16.

PRESENT—Messrs. Clayer, Wishart, Phillips, B. Arndt, W. Napier, F. R. Arndt, McGilton, Mitton, R. McCreanor, Sterrat, W. Pennyfield, J. Fiedler, R. Koska, C. Virgo, Fowles, Jarvis, Simon, E. Day, Hughes, W. R. Lewis (Hon. Sec.), and a number of visitors.

CULTIVATION OF IRRIGATION AREAS.—Mr. H. S. Taylor, of Renmark, delivered an interesting address. For the irrigated land on the Murray, he said, the Doradillo vine was a safe proposition. Mildura experience was cited to show the probability of an average yield of 10 tons of grapes per acre from vines receiving a reasonable amount of care. The demand for grape spirit was likely to hold for a good while, and South Australian winemakers would not trouble to make their own spirit while they could draw supplies from the river. The Goldmine and Stanwick nectarines were well adapted to the river and very suitable for drying purposes. Certain varieties of apples did very well, producing fruit of a uniformity of size which districts dependent on the rainfall could never hope to attain. The earlier ripening of the river fruit gave it a great advantage at the beginning of the shipping season, when cool chambers were often hard to fill. The varieties of apples specially recommended by the Victorian Department of Agriculture for the northern irrigation districts were the Gravenstein (on its own stock), Cleopatra, Dunn's Favorite, Rokewood, and Mellin's Seedling. The adaptation of the pear to riverside conditions was said to be amply proved. So far, the Williams or Duchess had been almost solely grown on the river for commercial purposes, and that mainly for drying. Under the pre-cooled system of shipment, the Williams was regarded in Victoria as one of the best pears for export purposes Other varieties recommended were the Glou Morceau and Josephine (both of which have done well in Renmark), the Buerre Bosc, and Packham's Triumph. With proper attention to its pruning—avoiding cutting back—the prune promised well on the river. The d'Agen, Splendour, Sugar Prune, and Fellenberg were the varieties most strongly recommended. The d'Agen should not be planted alone, as it needed cross pollination. The apricot, though much neglected of late years, gave promise of coming again Australian prices were very much better than in former years, and export prospects had enormously improved. There was also a good demand for it for canning purposes. Of peaches, the Elberta was recommended especially for canning. It was also a good drier. Heavier crops were produced by the Early Crawford, Salway, and Lady Palmerston. The latter two were also good canning varieties. Other good varieties were the Muir and Foster. For quickness of returns the peach was one of the best of the fruits. The Washington Navel was the best orange for the river, with the possible exception of the Thompson's Improved Navel. More attention should be given to the Mandarin, which came into bearing earlier than the ordinary orange and brought high prices. There had been a marked revival in the demand for lemons, and those trees, when liberally fertilised with animal manures, yielded enormous crops.

Fodder Crops.—Another result of the Victorian experiments was to demonstrate that crops of greater feeding value could be produced from the millets and sorghums than from maize. Maize, however, could be safely cut and fed at all stages of growth, and was especially valuable for ensilage purposes. When planted among young trees or vines these fodders should be set in rows of a sufficient width apart to allow of cultivation. Cow peas yielded a good bulk of fodder, and also made valuable green manure. The pods made a good vegetable dish, treated like French beans, and the seeds, when dried, could be treated like haricot beans. He always made a point of growing some in his own garden. Chou moellier was a variety of kale. Very good results were reported from its use at Nikalapka a couple of years back. Mangolds and beet were much relished by poultry, as well as by pigs and cows. They could be "pitted" or stacked when the tops had been removed, and would keep good for many weeks. For winter greenfeed barley would be found hard to beat. It should be sown with the autumn watering, and should give two or three good cuttings. A good deal might be done by growing potatoes and onions, especially the former, for which the country was well adapted, if the right varieties, such as Up-to-date and Early Vermont were planted. Local conditions were extremely favorable for the sweet potato and the Jerusalem artichoke. Both of these yielded very heavy crops, and would keep in the ground all through the winter. Artichokes were certainly a very valuable pig fodder. It was to the interest of the Government to see the settlers succeed. To further this object butter and bacon factories should be established as soon as any considerable number of settlers were prepared to keep a cow or two and a few pigs. The Government should endeavor, as was being done in New South Wales, to give the settlers every facility for acquiring really good dairy stock on easy terms. For success in dairying two things were essential. Good stock and plenty of suitable feed. The latter was easily supplied on an irrigation block; but to get really good stock was often a difficult matter. A striking illustration of what might be done by devoting an irrigation block to the growth of fodders for pigs and dairying was furnished by the experience of Mr. H. Jacob, of Mildura. Mr. Jacob had formerly 20 acres under trees, vines, and lucerne. He started pig-raising, giving the pigs very little besides green lucerne, and he found them pay so well that he rooted out all his trees and vines, with the exception of a little over an acre of lemon trees. The area under lucerne was extended and other fodder crops were planted. A few cows were also invested in. Heavy dressings of the pig and cow manure resulted in the land, which was not of first-class quality, yielding prodigious crops of maize, as also heavy crops of potatoes and other vegetables. Lemon trees which some years ago were yellowed and sickly and appeared to have outlived their usefulness were wonderfully revived by the droppings of the young pigs turned among them, and subsequently by dressings of cow and pig manure; so much so that they had for years been producing an annual crop of lemons of an average weight of 20 tons to the acre. The fruit from a fraction over an acre of lemon trees had yielded Mr. Jacob a net average return of £160 per annum for the last seven years, and one year's crop had realised no less than £250. That gentleman had extended the area of his holding to 50 acres, all of which, with the exception of the small patch of lemons, was devoted to fodder crops and stock. Mr. Jacob had informed him that his gross returns from the 50 acres came to £20 an acre. Of the 30 acres which he had added to his holding 20 acres were under lucerne (divided into eight paddocks, on which the cows pastured in rotation), and the balance was held for annual, or rather, semi-annual crops. All his land, except that in lucerne and the lemon patch, was made to yield two crops a year—of maize in the summer and oats or barley in the winter. The maize yielded up to 20 tons per acre, and the speaker had been shown a sheaf of maize, 12ft. in height, and one of Algerian oats 6ft. 3in. in height, which were grown on land that had been 23 years in continuous cultivation, and which for many years had yielded two crops a year. Potatoes of the Up-to-date variety yielded two crops a year. Last year the spring crop, sown on August 1st, gave a return of 4 tons to the acre, and the autumn crop, sown on February 1st, yielded 6 tons. Half an acre was reserved and used as a cowyard in which the cows were kept over night. This was made to yield a rich return. It was divided into two paddocks of a quarter of an acre each, and the paddocks were used alternately each half-year. The one not in use at the time was planted. Last summer £20 worth of pumpkins was raised on one of these one-quarter acre lots, and an equal return was expected from the other, which was planted with cabbages this winter. Mr. Jacob had now devoted himself almost entirely to dairying, having replaced most of his pigs by cows, of which he had 16 in milk. His place presented a splendid illustration of the possibilities of dairying on a comparatively small holding. One of the striking features of the farmstead was a round overhead silo, with a capacity of 60 tons. This had been built by the Victorian Department of Agriculture at a cost of £43, for the payment of which three years was allowed. This was filled every year with chaffed maize, and Mr. Jacob reported that the ensilage was eaten greedily by the cows, and that by tramping well round the edges of the silo as it was being filled all waste was avoided. Mr. Jacob had prepared a plan to illustrate his idea of the way a 30-acre irrigation holding should be utilised for fodder crops. The plan showed 10 acres (in blocks of five acres) out of the 30 under lucerne, which was to be cut and fed. The remaining 20 acres were divided into four paddocks, with a suitable reservation for farm buildings and feed lot. A couple of dams at the central corners of the paddocks allowed the stock to have access to water in each paddock. Paddock No. 1 was to be planted with maize on September 5th, and the cattle turned in to graze on January 1st. It was to be afterwards planted with barley and tares on March 1st and grazed on July 1st. In paddock No. 2, maize would be planted on October 15th, to be grazed on February 1st; barley and tares planted April 1st would be ready for grazing by August 1st. In paddock No. 3, maize planted November 15th would be ready for grazing by March 1st; and barley and tares planted May 1st could be grazed by the 1st of September. The last paddock would be planted with maize on December 15th, to be grazed April 1st; and oats and tares planted on June 1st would be available for grazing by October 1st. Thus, with the addition of lucerne hay and the grazing of the lucerne paddocks during the winter, a constant rotation of greenfeed might be secured. With the further assistance of a silo, such as Mr. Jacob possessed, the cattle need never be otherwise than well fed and in good condition.

Berri, October 13.

Present.—Messrs. A. P. Wishart (chair), S. Phillips, C. Foreman, E. G Mitton, S. L. Stearne, R. Arndt, A. R. Staehling. A. Jarvis, A. Simon, V. C. M. Fowles, E. Day, B. H. Arndt, J. Fiedler, W. Powell, J. McGilton, A. P. Wishart, R. Koska.

Pollination—Mr. Phillips read a paper on this subject. He described at length the structure of the flower, mentioning the functions of the sepals, petals, stamens, ovary, and pollen, in addition to the fruit. There was a general natural tendency, he said, for flowers to endeavor to prevent self-pollination. Plants that were cross-pollinated by means of the wind produced very large quantities of pollen. Insects, especially the bee, played an important part in this work also; the colored petals, secretion of honey, &c., being designed with the object of attracting these visitors Darwin, in an extended series of careful experiments, demonstrated that seeds cross-pollinated were more vigorous than those self-pollinated. Most fruits, such as apples, pears, quinces, apricots, peaches, plums, cherries, almonds, &c., each had five petals, five sepals, and many stamens. The ovary was divided into five cells in the apple, &c., and consisted of one cell in the almond and cherry. The fruits also differed, almonds having a leathery outer coat, enclosing the seeds. Plums, cherries, peaches, apricots, &c., had a thin outer covering, a juicy inner portion, and then a shell containing the seed. Apples, pears, and quinces had no shell surrounding the seed. The flowers were so open that numerous varieties of insects were capable of cross-pollinating them. Oranges, lemons, and citrons also bore large open flowers, and were consequently easily cross-pollinated by insects. With marrows, pumpkins, and trombones, the male flower was separate from the female, and in the absence of bees, it was necessary to brush the male flower against the stigma. Broad beans were frequently not pollinated, and consequently failed to set. When watermelons and pie-melons were grown in close proximity, there was a danger of hybridization, so that the seed of such should not be used for planting.

Claypan Bore, October 13.

(Average annual rainfall, 16in. to 17in.)

Present.—Messrs. J. Gray (chair), M. Robinson, S. Gray, J. N. Entwistle, E. Colwill, F. S. Tall (Hon. Sec.), and five visitors.

Harvester v. Stripper.—In a paper advocating the advantages of the use of the harvester, Mr. M. Robinson said it was labor-saving, and a much safer way of dealing with the crops, as the wheat could be removed at once from the paddocks. It was alleged that this machine dirtied the land, but it only replaced seeds of weeds that were already there. It carried the wheat on the near side of the machine, and equalised the draught, whereas the stripper carried the wheat behind the combs which caused it to run sideways. In a competition carried out on Yorke's Peninsula, where a harvester and stripper went round for round through a crop, it was found after the wheat from the latter was motor winnowed that much more clean wheat was gathered by the harvester. Clean bound straw was better than cocky chaff for feed. With ordinary care the harvester should last for 12 or 15 years.

Mr. S. Gray contended that owing to the stumpy and sandy nature of the land in the district the stripper and power winnower were the best means of harvesting a crop. Where the harvester was used, in a crop where the mallee was high, the leaves repeated through the machine and the grain became bespattered with juice: after standing in the hot sun for a few days it would sweat. Cocky chaff mixed with molasses and pollard made good feed for young stock and idle horses. A stripper with a good sharp beater could start as early in the crop as a harvester. The former could also be put into the crop two or three days earlier than the latter, as the grain ripened in the heap. Strips of tin about 2in. deep and 15in. long fastened to the inside top of the stripper would direct the wheat to the near side, bringing the load directly behind the horses. Mr. E. Colwill advocated using both machines. Mr. Entwistle favored the stripper, and the Chairman thought the harvester was best capable of dealing with crops of 12bush. or over.

Coomandook, October 11.

(Average annual rainfall, 18·01in.)

Present.—Messrs. W. Ninnis (chair), A. Bald, H. Gosden, N. Brown, L. Crouch, J. Brown, J. Bald, C. Mitchell, P. C. Potter, A. Ritchie, R. William, W. Brown, C. Hillman, H. Hughes, F. Cordes, M. Wilkin, C. M. Wilkin (Hon. Sec.)

Breeding and Care of Horses.—Mr. A. Bald read a paper in which he said the most suitable class of horse for farm work in this district could be secured by mating good draught mares to roadster stallions. The result would be a horse with a good body and fairly clean legs. It would stand plenty of work, especially on the roads, and would walk quicker than draught horses. In the absence of plenty of good feed in the paddocks mare and foals should be provided with chaff and bran and a sprinkling of oats. As it was difficult to get a good cut of hay in this district it was a good plan to sow a considerable area of oats and strip this, bagging the grain without cleaning it. This could be fed to the horses at the rate of one bag mixed with three bags of cocky chaff. While some members preferred the heavy draught, the majority favored the medium draught with clean legs as the most suitable for this country Mr. Peake thought better and more saleable foals would be secured from draught stock. Members thought oats and cocky chaff good feed when hay was scarce, but the majority favored cleaning the oats, not bagging it direct from the stripper. It was a good plan to crush the grain. Water should be available in the yard to the horses at all times.

Coonalpyn, October 17.

(Average annual rainfall, 17·49in.)

Present.—Messrs. A. J. R. Gurner (chair), H. Bone, J. Hill, G. H. Wall, E. E. Williams, R. F. Venning, J. J. Cronin, D. S. Cronin, F. Pitman, G. E. Venning, and eight visitors.

Lime-Burning.—A short paper on this subject was read by Mr. J. Hill. For burning lime, he said, an excavation about 10ft. across and 7ft. deep should be made in the earth, with a smaller hole on one side to facilitate lighting the fire. The latter should be so situated that water would not run into the kiln. A bed should be made of dry twigs, with a few roots to take the weight and ensure the fire spreading evenly. Then a layer of about 2ft. of dry roots, well trimmed, should be added. On this the moderately hard stone could be broken to about 6in. in size. The stone should be kept somewhat heavier in the centre. Another layer of well-trimmed green roots should be added, and then a heavier layer of stone, broken to about 4in. Alternate layers of roots and stones should follow, the top layer of the latter being about 2in. in size and about 3ft. above the surface of the ground. When the fire was well alight the bottom draught should be blocked. Mr. F Pitman advised lighting the kiln by forming a hole about 8in. in diameter in the centre. It was very necessary to keep the heat down. Mr. Wall thought sandalwood and green mallee better than mallee roots for lime-burning.

Lameroo, October 18.

(Average annual rainfall, 16·55in.)

Present.—Messrs. Cameron (chair), Mayo, Jericho. Dragomuller, Tink, Wray, F. W. Eime, Martin, Kakoschkie, Koch, Davison, Cameron, E. J. Trowbridge, Gibbons, Ross, Townsend, S. G. Trowbridge (Hon. Sec.), and two visitors.

The Agricultural Bureau.—The Chairman read a paper under the title "The Advantages of Becoming a Member of the Agricultural Bureau." He dealt at length on the educational benefits to be derived from active association with this institution, and mentioned the excellent opportunity which it afforded of bringing the farmer in direct contact with the agricultural expert. Members discussed the paper, and Mr. Koch expressed the opinion that a great deal of good would be done if more experimental work were undertaken by members.

Takeall.—Mr. E. J. Trowbridge reported that he had 20 acres of crop on well-worked fallow badly affected with this fungus. Where oats had been grown previous to fallowing the crop was unaffected. Members agreed that the practice of sowing oats on land likely to carry crops troubled with this disease was advisable.

Monarto South, September 13.

(Average annual rainfall, 14in. to 15in.)

Present.—Messrs. G. Patterson (chair), A. P. Braendler, J. and H. Frahn, A. Forbes, G. Gogol, A. Harper, A. and E. Hartmann, G. R. and B. Paech, G. Thomas, A. Schenschen, C. F. Altmann (Hon. Sec.), and 10 visitors.

Takeall.—In a paper on this subject, Mr. A. Hartmann said the practice of cropping every fourth year and grazing during the intervening period kept the land in good heart, and discouraged takeall. There was also less trouble with this disease in stiff and loamy soils if they were cultivated after rains during June, July, and August. Cultivation when the land was dry seemed to encourage it. Dressings of phosphate and lime immediately after fallowing increased the yields, and kept the crops free of the fungus. When land was cropped every second year, the first crop should be wheat, then grazing, the third year oats, fourth grazing, and then wheat; a crop of wheat being secured every fourth year. One member thought a good stubble burn very effective in preventing the disease.

Morgan, October 11.

(Average annual rainfall, 9·29in.)

Present.—Messrs. R. Wohling (chair), O. Hausler, J. B. Hoffman, J. Heppner, C. H. R. Wohling (Hon. Sec.), and one visitor.

Pig-Raising.—The Hon. Secretary read a paper on this subject. He recommended the Berkshire-Essex cross as a good paying animal. The pure Berkshire was difficult to keep in condition. On the other hand the Essex was easily kept in condition, carried a light coat of hair, and was easily dressed when killed. The flesh was tender. He preferred to have the sow farrowing in October or November. The sow should not be under 12 months old and the boar 15 months old when breeding was commenced. Immediately after farrowing the sow should be fed for three or four days on sweet milk and pollard, green lucerne being given in the morning only. After harvest he made a practice of running the pigs on the stubbles until seeding, when they were marketed. He had found the business profitable. The Chairman mentioned that the prickly pear, finely chopped up, made good summer feed for pigs and poultry.

Parilla, October 9.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. H. G. Johnston (chair), E. J. Kerby, H. W. Harrip, J. H. Daniel, M. J. McAskill, J. Roachock, P. W. Lewis, M. Shannon, A. J. Stevens, C. Foale, P. Harrip, C. Moyle, M. Rush, S. H. Evans, G. E. Gregory, G. Neindorf, C. Millsteed, J. H. Dewhurst, P. J. Browne (Hon. Sec.), and eight visitors.

LUCERNE CULTIVATION.—An interesting address on this subject was delivered by Mr. J. H. Daniel. Four different growths of lucerne were exhibited. One had been sown two years ago and sprinkled at various times. During the past 12 months it had been cut on eight occasions. Five weeks ago it was cut level with the ground, and at the present time was looking extremely well and had reached a height of 2ft. The second sample was from a plot of four acres, sown on the 6th August last year with a crop of wheat at the rate of 10lbs. to the acre; 25cwts. of hay per acre had been cut from the area. The lucerne was cultivated six weeks ago and was now 9in. in height and very thick. This plot had not been irrigated and little rain had fallen on it. The third sample was from an area sown at the rate of 1lb. of seed per acre. The plant was very vigorous, and indicated that if the practice of distributing seed in all the paddocks were followed, excellent fodder for stock would be secured. The fourth sample was from a plot sown at the rate of 3lbs. per acre with a hay crop. The lucerne averaged from 6in. to 12in. in height and gave every indication of providing excellent feed in summer. The method of sowing recommended by Mr. Daniel was to take the tubes out of the hoes of the drill and spill the seed on to the surface of the ground, following which, some light bushes should be dragged over the surface sown. The lucerne should be mixed with the manure and put in after the grain was drilled. Mr. J. Lee thought it better to cut the lucerne than to feed it off.

HAY-MAKING.—Mr. B. G. Neindorf read a paper on this subject. Wheat, he said, should not be cut for hay until the grain had nearly matured, as if cut too green it would lose weight. Oats should not be cut until nearly ripe, otherwise the hay would be bitter. The sheaves should be stacked in long rows, and if there was little danger of wet weather, they could be placed flat on the ground. They would then lay closer than if stood up. The hay should remain in the stooks for 14 days before being carted, but if the stooks were put flat on the ground it could be stacked somewhat earlier. Long stooks were best, as rain did less damage to them. Care should be taken not to commence the stack too large. For wheaten hay, he preferred White Tuscan or Majestic. When carting, it was advisable to take small loads that could be thrown out quickly. A large tightly tied sheaf was much easier to handle than a small loose one. The best hay was secured by first drilling in wheat and then cross-drilling with oats. In reply to a question he said that hay could be left in the paddock for a couple of days before being stooked, and should not be stacked until it was dry enough to break or crack when bent. Mr. J. Gray (Chairman of the Claypan Bore Branch) said that if the crop were allowed to stand long enough for one to secure the benefit of the grain, the best part of the saccharine in the straw was lost. When a good rain fell just about hay harvest time, the crop could be cut at a much greener stage, as the grain would ripen in the heads after it was cut. Sydney chaff buyers preferred hay that was cut green. Corn could be made up with the addition of bran. Mr. McAskill considered hay cut on the green side the best for stacking, but when intended for market, it should be cut a little later, as it weighed better. Mr. Daniel recommended cutting the crop when the bloom had gone off, and the wheat was in a forward milky stage. The saccharine was then distributed over the full length of the straw. Mr. Johnston said more weight was secured if wheaten hay were left until the grain was full. Oats, which were preferable for feeding to working horses, should be left until the grain was almost ripe.

Parrakie, September 13.

(Average annual rainfall, 16in. to 17in.)

PRESENT.—Messrs. T. Lewis (chair), F. Brinkley, R. L. Beddome, T. P. Congdon, S. R. and W. J. Good, C. Heinzel, R. E. Jose, C. Nadebaum, W. Threadgold, J. G. Temby, H. Diener (Acting Hon. Sec.)

IMPLEMENTS.—Mr. J. G. Temby opened a discussion on the advantages of using draught springs on tillage implements. By using a draught spring bridle plough, he said, the horses' shoulders would not be jarred any more than if a spring pressure implement were used. The swings would carry much steadier, and this was a big advantage to a team. He was of the opinion that a four-furrow spring was strong enough for use behind seven horses, as a spring with more resistance would be nearly ineffective. On a scrub roller it minimised the danger of breaking trace chains, and he recommended its use on harvesters. Mr. Beddome used a six-furrow spring behind seven horses in the plough and roller, and the horses were less troubled with sore shoulders since he had been using the springs. Mr. Jose had used a four-furrow spring behind eight horses when ploughing heavy land in the middle north. Mr. Threadgold thought a five-furrow spring was strong enough to put behind eight horses, and anything larger was too strong. There was a disadvantage in its use, however, as it placed the horses too far away from their work. Mr. Congdon favored the use of a strong spring, because one that closed right up was of no benefit. It would let the farmer into the trouble he was trying to avoid. Small springs could be used more in the tugs on tip drays and English wagons.

Pinnaroo, October 11.

(Average annual rainfall, 16·74in.)

PRESENT.—Messrs. P. J. Edwards (chair), A. M. Burman, F. G. Bonnin, M. H. Chappell, R Edwards, H. G. Fewings, L. M. Ferguson, H. C. Hill, G. E. Hallett, W. H. Kelly, C. Lee, H. Ledger, J. Letheby, B. H. Nash, A. J. Reed, J. Scales, T. B. Shiels, H. Venning, and P. H. Jones (Hon. Sec.).

BREEDING AND HANDLING HORSES.—Mr. R. Edwards dealt with this subject in a paper in which he said good horses were necessary and there was no room for the lean, lanky, creature, neither draught or light "A thoroughly good sire," he said, "is the most important factor. It is more profitable to pay £4 or £5 for the use of a good horse than £1 or 30s. for the services of a mongrel and a second-rater. I favor the short, thick-set sire with plenty of vitality and showing good bone and hair and not set too high If a well-bred sire of a stamp as described is used it matters little about the pedigree of the mare so long as she is a fairly well-proportioned and roomy animal. On no account would I breed from a jib or a mare with a vicious temper. I consider the best age to mate a mare is at about 3 years, so that she drops her first foal at 4 years or thereabouts. I would have the mares alone when foaling, away from all geldings and youngsters, as many a good foal has been lost through the interference of other stock. However, a strict watch should be kept on them from a distance, so that if anything should go wrong it is at once detected. For this reason I favor a paddock not far from and in full view of the homestead. If this is not possible they should be looked to first thing every morning and last thing at night. When the foals are dropped the mares should be well fed and looked after and stabled should the weather become wet and cold. Allow the foals in the stable with their mothers as much as possible, as this not only tends to quieten, but teaches them to readily drink from the trough and eat from the manger. Rock salt should always be at hand for both mothers and foals. Weaning should take place at from six months to eight months. I favor taking the foals straight from the mares and not allowing them one drink a day for a while as many people advise. This only prolongs the agony and tends to keep up the milk supply rather than diminish it. Occasionally a mare is troubled with an excess of milk, but not often. It is generally necessary to milk a little from them for a day or two. If there is an extraordinary supply at weaning time, as is sometimes the case, it will be found that bathing the udder in a strong solution of salt and water will very soon overcome the difficulty. If possible, the foals should be put in a small paddock with plenty of natural feed. They will naturally go back a bit, due principally to fretting. They should have all they can eat of good feed with a liberal allowance of corn. I favor oats for growing colts. It is advisable to keep the foals separated from the mares for at least three months, as a badly weaned foal is always a nuisance. When yearlings, or about September, they should be brought in for branding and castrating. For the former I prefer to rope the colts rather than use a crush pen, as it is all valuable education, and will go a long way towards preparing them for breaking-in. On no account would I brand when the animal is down, for though the front legs be not tied it is difficult to get the exact position, and it often results in an altogether illegible brand. I prefer the emasculator to the clamp and searing irons for castrating, as it is much quicker, and the suffering and straining in the ropes is much lessened. Hot, windy weather should be avoided for this operation and a calm, warm day selected. Thorough cleanliness should also be strictly observed. The colts should never be short of feed right up to the time they are broken in, and even after. Break them in at 2½ years for ordinary farmwork. I do not like breaking at 2 years as the weather is usually hot and the youngsters get very much distressed over their work; and apart from that, if broken at 2 years, or just before harvest, there is a tendency to overwork them through the extra busy period. Many farmbred colts can be caught in the stable alongside a quiet horse; but failing this I would rope round the neck with a slip knot and draw the animal to a stout post. Put on a halter by which the horse can be held or led. On no account put on the winkers until all the other harness is in place, as I believe in letting the horse see all that is going on around him. It may take a little longer to get the harness on for the first time or two in this way, but the animal soon gains confidence, knows exactly what to expect, and becomes tractable. If the winkers are put on first he will naturally jump every time he catches sight of the operator, and this will encourage nervousness. If possible avoid all rough handling, particularly in the early stages, as it takes a colt a long time to forget a thrashing. Patience is a most important factor. When a good fitting collar and hames and a strong pair of winkers have been put on the colt should be led about until he becomes used to the harness, and then put between two old horses and drive round, always leaving the halter on in case of accident. If he is at all troublesome it will be found a good plan to couple the horses from the neck as well as the bit, having the neck couplings a little tighter than those on the bit. This takes a large amount of the strain and irritation from the naturally tender mouth. A sore mouth is often the cause of quite a display of vice. Generally speaking, if a colt is farmbred, after being driven awhile in this manner, he will go straight into the team; but if not considered quiet enough for that he may, with advantage, be attached to a light log and allowed to pull that about for awhile. Half a day's work is quite sufficient at first until the horse becomes used to it and gets a little hardened. Then he may do a full day, providing it is not too heavy. I do not favor working youngsters too hard for the first six months. When brought in from work the shoulders should be washed with a weak solution of Condy's fluid. This not only cleanses but toughens the skin, and if a well-fitting collar is used there should be very little danger of scalding or sore shoulders. Avoid all risks when a colt is in the team as he rarely forgets a runaway or a general upset. Every care should be taken not to excite him more than necessary, and to keep him as quiet as possible. It must be remembered that he has everything to learn, and too much should not be expected of him at first. After working in chains for a while it is a good plan to put him into the shafts of the wagon and change him about till he becomes used to all kinds of farmwork. If this plan is adopted one will never be met with the difficulty of having a horse who will only work in one particular place." Mr. Ledger was strongly in favor of breeding from pedigree stock. An animal from a good strain often left stock of a better quality than the good-looking animal without a pedigree. He always accustomed his foals to tying up when about three weeks old, as they were then far less trouble when it came to the time of handling. Youngsters did not need corn; preferably he would feed on hay cut on the green side. It was wise to get the animal used to one place in a team. Certain of his horses had never worked but in the one position, and he found it a great advantage. Mr. Scales believed in handling them when 2 years of age, as they would then be ready to take their place in the team at seeding-time. It was inadvisable, however, to put the horse to heavy labor during the early stages of its education. It did not matter much whether it was broken at 2 years or even 4 years. It was the treatment subsequent to handling that was the most important point. He had never found it necessary to keep the foals away from the mares for three months during weaning. In most cases 14 days was sufficient. Mr. Ferguson favored the open bridle in preference to winkers. He would apply the brand so that it came below the chain draught. Mr. Lee thought light work and kind treatment two essentials which must not be overlooked. Mr. Shiels remarked that in handling young stock a lot depended on common sense. Numerous factors prevented any hard and fast rule as to just when a colt should be weaned and handled. Individual cases must receive special attention. Mr. Venning would first handle horses at 2 years, and then turn them out again for several months before putting them to general work. He favored the use of the open bridle. A horse should be taught to stand and start. Mr. Chappell did not care to give oats to young horses, he preferred bran. That fodder was the best that could be given for the making of bone without fear of overheating. When breaking he would not join by the bridle coupling; this was too much of a jar on the tender mouth and often was responsible for old horses throwing up their heads. He would join them with neck ropes until they were accustomed to the surroundings

Waikerie, October 13.

(Average annual rainfall, 8·89in.)

Present.—Messrs. E. J. Burton (chair), R. Stanley, F. B. Williams, W. J. Green, F. G. Rogers, J. J. Odgers (Hon. Sec.).

Weather and Crops.—It was reported that the weather during the month had been very dry, and during the week immediately preceding the meeting, exceedingly hot, but a good rain was falling, and this promised to continue. There was an exceptionally good flowering of oranges; and peaches and apricots had set splendidly and promised a good yield. Wheat was looking remarkably well, especially on early sown fallow. Hay-cutting had been commenced, one member reporting a yield of one ton to the acre.

SOUTH AND HILLS DISTRICT.

Blackwood, October 13.

(Average annual rainfall, 27in. to 29in.)

Present.—Messrs. W L. Summers (chair), Wilson, Scherer, Eglinton, A. W. and A. A. Magarey, P. H. and D. Williams, Sibley, Porter, Penno, G. W. Summers, Philps, H. Sullivan, Winser, Davis, Goutch, Hilfers, Gamble, and Savage (Hon. Sec.).

Potatoes.—Mr. D Williams contributed a lengthy paper in criticism of articles appearing in the July, August, and September numbers of the *Journal* on the subject of potatoes. He mentioned that in cutting smooth tubers that had a crown of eyes, as it were, it was always advisable to include one of these eyes in each set. Round seed was best, as it did not rot so readily with excessive moisture. Lime should be added to land for potatoes in this district, and manures should be worked well into the soil before the crop was put in. Earthing up should be done when the plants were 3in. or 4in. high, the second hoeing being about a fortnight later.

Manures.—Mr. A. A. Magarey also dealt critically with articles on manures appearing in the last three issues of the *Journal.* The following is taken from his paper:—"In dealing with this subject, we should understand the connection between the chemical requirements of the plants and the part played by soils and manures in supplying these. We will not be far wrong if we assume that all plants are built up of the same elements combined together in different proportions. These are carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, silicon, chlorine, and about half a dozen metals in combination. For example, different combinations in varying proportions of carbon, hydrogen, and oxygen give us that large class of bodies known as carbohydrates, including such unlike substances as starch, sugar, woody fibre, cellulose, gum, &c. Hydrogen and oxygen combined give us water; nitrogen united with the above elements forms the nitrogenous constituents of the plants; for instance, gluten in wheat and the albuminous matter in the pips and seeds of fruit. Very little is known of the metals, their disposition in the plants, and the changes they undergo. We are able to detect their presence in the ash in combination with oxygen, phosphorus, sulphur, and chlorine. The quantities of the elements not only vary in different plants, but in the same plant some elements are present in quantities out of proportion to the others. More than one-half of the bulk of all growing plants consists of water. In watery fruit, such as watermelon or cucumber, the percentage of water would be from 90 per cent. to 96 per cent. Of the remaining portion of the plants the compounds of metals rarely exceed 2 per cent., and are more often about 1 per cent. The point of importance for us to keep in mind is, that each of these plant constituents is as necessary for the wellbeing, even for the existence of the plant, as any other, whether present in the plant in large or very small quantities. If a single one of the ash constituents is insufficiently supplied, if the potash is deficient, or the iron, the plant suffers, although the amount of such element does not exceed a fraction of 1 per cent. The volatile portion (that is the part that is burnt away, leaving the ash) of the plant, the water carbohydrates and nitrogenous matter is for the most part abundantly supplied by the air and rain (with the exception of the nitrogen in some plants). That is to say, about 98 per cent. of the plant food is derived from air and water. From the soil the plant gets the remaining 2 per cent., consisting of lime, iron, magnesia, potash, soda, and perhaps manganese combined with sulphuric, hydrochloric, and phosphoric acids, together with nitrogen as already stated. These substances it is the function of the soil to supply. The object then of manuring is to assist the soil in giving to a plant a portion of the food necessary for its growth. Of the ingredients to be supplied by the iron, magnesium, sodium, manganese, chlorine, sulphuric acid, and silicon are present in nearly all soils in far greater quantities than the plant requires, so that there is very little danger of their becoming exhausted. The ingredients that we have to supplement by means of manures are reduced to four, namely, lime, potash, phosphoric acid, and nitrogen. Lime is probably present in most soils in quantities sufficient for plant food, and it is seldom necessary to apply it for that purpose. Its principal functions when applied to the land are, firstly, mechanical, in modifying the physical character of the soil, and, secondly, chemical in rendering available certain insoluble plant foods. Lime acts also, however, directly as a plant food. The different classes of artificial manures fall under one of the above headings, according as they supply lime, potash, phosphoric acid, or nitrogen. The food thus supplied by the soil is taken up in solution by a peculiar process of suction by means of the roots. It is therefore necessary that such food should be in a soluble form to be of any use to the plants, which are unable to use insoluble material. By soluble we mean soluble in water or weak acids present in the soil, or secreted by the plant roots. This is what is meant by the mineral constituents being 'available for plant food'; and when the terms 'latent' or 'dormant,' and 'active' are used, they simply mean insoluble or soluble in the water taken up by the roots of the plants. The manures known as quick-acting manures are those containing their potash, &c., in a soluble form, and slow-acting manures are those which contain these substances in a more or less insoluble form and must undergo a gradual decomposition before their phosphoric acid, potash, &c., are available for plant food. A good example of a quick and slow acting manure is found in the state of the phosphoric acid in superphosphate and bonedust. From the foregoing we can see that all plants do not take up the constituents supplied by the soil in the same proportion, and consequently are benefited differently by different manures. For instance, no amount of nitrogenous manure will materially benefit a pea crop, but a small quantity added to land in which wheat is to be grown will largely increase the yield. In connection with the application of artificial manures we have the following points to consider:—(1) What are the chemical requirements of the different crops? (2) In how far do our soils supply these requirements? (3) In what direction are they to be assisted by manure? Plants, like animals, give the best results when fed in a rational manner. They require a constant supply of plant food during active growth, and if we put a heavy dressing of manure on the soil one year, the trees are only able to use what they require for that season's growth, and during the winter a large proportion of the manure is leached out of the soil and lost. For the next year or two the trees are very apt to suffer from the lack of the very plant food this manure was intended to supply. This applies more particularly to the active manures. On the other hand, if we applied just sufficient manure each year for the trees requirements, very little would be lost by leaching, and the trees would do much better for the same amount expended. Difference of opinion exists as to what is the best time to apply manures in the orchard. This is a matter that is well worth experimenting with to find out what is really the best practice. As a general rule slowly soluble manures should be applied sometime before they are actually required for plant food, say some time in the autumn. Soluble manures, such as superphosphate, sulphate of ammonia, nitrate of soda, nitrate of potash, sulphate of potash, &c., should not be applied until the tree is in active growth, if possible, that is in spring. For if they are applied to the soil any time before they are required they are apt to be leached out by heavy rains before the trees are in a position to use them. In parts that have summer rains it might be advisable to apply the more soluble manures in two or three dressings, at intervals of a month or two, but in this district I hardly think that necessary. Nitrogen is required for the albuminous matter in fruit, and this occurs in largest quantities in the pips and kernels. Potash forms the largest proportion of the ash of the fruits, and phosphoric acid is essential to all fruit, forming a large proportion of the seed in which respect it is similar to nitrogen. In a paper on page 1450 of the July, 1913, issue the writer places the value of farmyard manure at 9s. 9d. per ton This estimate is based on the amount of phosphoric acid, potash, and nitrogen contained in the manure, but we have also to take into account its value in improving the mechanical condition of the soil. Farmyard manure to be of any real value must be properly kept. The writer states that 'nitrogen, the most valuable part of the manure, is difficult to obtain.' This loss of nitrogen can be overcome by proper care. The temperature of the manure in fermenting should not be allowed to rise higher than about 86°, the rise of temperature can be prevented by pressing the manure well together and by pouring the liquid over it. Humic and ulmic acids are formed, which unite with and fix the ammonia and potash. Gypsum prevents waste of nitrogen and kainit, if added, will fix the ammonia. If the manure is allowed to overheat the ammonia is lost. Unless farmyard manure is well rotted before being placed in the orchard it is liable to spread many undesirable weeds. Spread it over the ground and plough it in some time in the autumn It is better suited for crops where rank growth is desired than for fruit trees. Cabbages, &c., do particularly well with farmyard manure. Lime unites with clay, setting free potash and other alkalies. It acts on vegetable matter, setting free ammonia, water, nitric acid, and carbon dioxide, with which it unites, tending to destroy excess of humus. It neutralises organic acids (humic, ulmic, geic, &c.), thus sweetening the soil and decomposes excess of ferrous sulphate; takes up nitric acid as formed by nitrifying bacteria. It is a plant food itself. It aids in the formation of secondary silicates. It opens up clay soil by the curdling or floculating effect it has on the particles, and binds together sandy soils, makes them more retentive. Lime also renders harmless injurious salts of copper, iron, &c. Quicklime should be applied to all clayey and humus soils, but lighter soils are best treated with a mild form, such as marl. Lime has a tendency to sink into the soil, and should be spread on the surface and harrowed in. The old style was to give heavy dressings at long intervals, but the present practice is to give light dressings more frequently. Green manuring must not be overdone, because the soil is liable to become sour with the excess of organic matter. A good plan is to sow lime just before the crop which is to be ploughed in. The lime, besides neutralising the acids, fixes the nitrate salts which are formed as the crop decays. At Renmark they disc over the crop and let it dry before ploughing it in; they claim that this prevents the land becoming sour. About the best crop on the whole to grow for green manure is field peas. Berseem may be all right but has not been tried in this district, the seed is probably too expensive. Field peas planted with the first rains will ordinarily mature in time to be ploughed under." The Hon. Secretary stated that Berseem had been grown at the Government Orchard last year as a manure crop, and although the autumn rains were deficient the Berseem made good growth for ploughing under.

Orchard Work.—Papers on this phase of agricultural activity came in for criticism by Mr. R Eglinton. Where tree-planting was to be done in good, deep soil, he did not think it necessary to use the two-pronged pick, as advised by the Horticultural Instructor; the ordinary grubber might be used. He agreed that root crops could be grown without damage to the trees whilst they were young, but cereal crops, even in narrow strips, as had been advised, should be left alone. Ploughing preparatory to planting should be as deep as possible. It was not advisable to put grass, &c., round the trees to assist in the retention of moisture, as this harbored disease, and encouraged the roots to grow near the surface. More attention could well be given to the planting of prunes. The best time to prune old apple trees was when a full crop was expected.

Cherry Gardens, October 14.

(Average annual rainfall, 35·03in.)

Present.—Messrs. H. Jacobs (chair), C. Lewis, C. Ricks, T. Jacobs, sen., G. Hicks, A. Broadbent, S. W. Chapman, T. Jacobs, jun., J. Tozer, H. and C. Jacobs, and H. Lewis

Potato-Growing.—In a paper on this subject Mr. C. Lewis said that for this crop he preferred seed that was just ready to shoot, and of a size that could be conveniently cut into three sets. The ground should have a good coating of stable or cowyard manure, which should be ploughed in to a depth of about 9in. during the dry weather. It should be again ploughed before planting. If it were intended to dig the area before planting, oats, wheat, or barley could be sown for greenfeed or for digging in. The potatoes should be put in rows 2ft. apart, with 1ft. between the sets in the rows. The use of the dibber was the best and quickest way of planting. Immediately the plant showed through the ground it should be well harrowed, and when the rows could be seen, hoed. Banking should be done a fortnight later. This would assist in destroying the weeds and facilitate the work of digging.

Forest Range, October 2.

(Average annual rainfall, 35in. to 36in.)

PRESENT.—Messrs. W. McLaren (chair), J., F., and E. Green, E. Rowley, H. Sass, R. Collins, O. S. Pollard (Hon. Sec), and one visitor.

BORDEAUX MIXTURE AND OTHER FUNGICIDES.—A discussion took place upon a bulletin issued by the Department of Agriculture and dealing with fungicides and Bordeaux mixture. Members thought the formula given for Bordeaux mixture, viz., 6lbs. bluestone, 4lbs. lime to 40galls. of water, too strong. They favored 4lbs. bluestone, 4lbs. lime to 50galls. of water, and for Burgundy mixture they recommended 2½lbs. bluestone and 5lbs. soda to 40galls. of water. There was a diversity of opinion as to whether Bordeaux mixture caused the rusty appearance on Jonathan and Williams' Favorite apples. Some members contended that it did so regardless of the strength of bluestone used. Others had noticed apples that had never been sprayed for fungi affected in this way.

Gumeracha, September 16.

(Average annual rainfall, 33·30in.)

PRESENT.—Messrs. B. Cornish (chair), A. Moore, J. Monfries, A. W. Cornish, T. Redden, and W. B. Randell.

COMPULSORY DIPPING OF SHEEP.—Mr. B. Cornish read a lengthy paper in which he drew attention to difficulties which arose in connection with the dipping of sheep, both, in so far as the law itself was concerned and in the administration of it. In order that these might be removed he made the following suggestions:—"(1) As there may be pastoral areas in the Far North where different conditions exist, the State should be divided into districts (not necessarily small ones). Wherever ticks or lice are found such parts should be declared infected districts. (2) In all infested districts every person who owns, or is in charge of a sheep shall, within, say, a month of shearing that sheep, cause the same to be properly dipped in a preparation made for the purpose, and of such strength as shall fulfil the instructions of the maker as to the strength required for effectually destroying all vermin that may be found on such sheep. (3) The work of inspectors shall be to see that this is well done. There will then be no vermin worth troubling about. (4) Every sheepowner who dips on his own premises should be compelled to make a declaration that all his sheep have been efficiently dipped. This would be sufficient in his case, because the one who goes to the trouble and expense of erecting appliances would scarcely then fail to make good use of them. (5) Any sheepowner not having appliances of his own shall cause his sheep to be dipped at some convenient place, and shall produce a certificate duly signed by the owner of such dipping pens showing that his sheep have been efficiently dipped. (6) No owner of any sheep shall, after shearing such sheep, sell the same, nor have it any public place, nor travel it on any public road, except to or from his own pasture, or for the purpose of dipping, until such sheep has been properly dipped. These regulations would not entail hardship on any one, as one or two dipping yards in one district where flocks are small would be sufficient. Arrangements could, no doubt, be made with the owners for use of yards for a fee to be agreed upon in a district. Sheepowners, as a rule, are fairly generous, and in our district have provided yards for nothing; but that is too much to expect, as these yards are somewhat costly to make and keep in order. The time occupied in dipping, say, a hundred sheep, is very little, perhaps half an hour where yards and pens are convenient, and the dipping is really a distinct benefit to the sheep. It is a splendid remedy, or rather, preventive of the blowfly. I have never yet lost a dipped sheep from this trouble." Members generally concurred that the difficulty could be overcome by all sheepowners dipping their sheep immediately after shearing.

Hartley, September 19.

(Average annual rainfall, 15in. to 16in.)

PRESENT.—Messrs. B. Wundersitz (chair), W. Bermingham, F. Lehmann, A. Wundersitz, P. Wagenknecht, T. Phillips, D. Clark, F. Bruns, J. Hudd, B Klaebsch, H. Cross, S. Beavis, J. M. Hudd, A. Stein, J. Stanton (Hon. Sec.), and 18 visitors.

HOMESTEAD MEETING.—The holding of Mr. J. Hudd was inspected by members and visitors. Whilst the crops were not as promising as usual on account of the somewhat dry season, some of the members estimated a return of about 16bush. of wheat and a cut of one ton of hay per acre. The Chairman of the Advisory Board of Agriculture, Mr.

G. R. Laffer, delivered an address, and expressed his pleasure at the large attendance, especially of young men. Messrs. W. F. Adams, C W. Taylor, and J. Stanton also spoke expressing appreciation of the efforts of Mr. Hudd in making the gathering enjoyable.

Hartley, October 15.

(Average annual rainfall, 15in. to 16in.)

Present.—Messrs. B. Wundersitz (chair), S. Beavis, H. Cross, P. Wagenknecht, J. M. Hudd, W. Bermingham, S. Pratt, A. Stein, F. Lehmann, F. Bruns, J. Hudd, J. Stanton (Hon. Sec.), and one visitor.

Afforestation.—Mr. S. Beavis read a paper on this subject. In nearly all countries of the world attention was being given to this subject, he said, and with the increase of population in Australia, large quantities of timber would be required for railway sleepers, building purposes, mining, furniture, &c. Unless the timber which had been destroyed was replaced there would be a considerable shortage. He recommended leaving belts of trees around the farms when they were being cleared, and in the absence of natural timber, planting trees for shade and shelter. The planting of trees in the streets as had been done at Orroroo was an excellent idea. It was hard to understand why large tracts of country in this State were not being planted with jarrah, sandalwood, and ironbark, and other timbers of commercial use that could be profitably grown. It was thought by members that this district was rather too dry to secure a profitable growth of timber, as the trees would take too long to mature.

Inman Valley, September 13.

(Average annual rainfall, 26in. to 27in.)

Present.—Messrs. H. J. Meyer (chair), H. J. Dennis, H. J. Jagger, R. J. Martin, V. G. Tugwell, R. Rose, F. J. Barratt, M. J. Meyer, T. G. Rose, and H. M. Parsons (Hon. Sec.).

Sheep and Wool.—Mr. M. J. Meyer read a paper on this subject, as follows:—"The most profitable industry in this district is sheep-breeding, and the three sources of profit connected with it are—wool, fat lambs, and mutton. The best returns cannot be obtained from working the three together. In raising fat lambs for market it must be borne in mind that the best woolled class is not the best fattening class. The lighter woolled varieties, such as the Shropshire, Southdown, Dorset Horn, or Leicesters are more suitable. Wool and mutton can be successfully managed, and, taking climatic conditions here into consideration, are the two main sources of profit. The aim of every sheepowner who wishes to get good results should be to find out the most suitable class for his country, and keep as near as possible to that. This will count a great deal in the get up of the clip at shearing time. Always keep the best sheep, as a good one will not cost any more to keep than the inferior. Never overstock, because partial starvation at any time of the year affects the growth of the wool. More could be done in this district, in the fat lamb industry, by the cultivation of peas for topping up the lambs. They could be produced just at the time when the earlier districts were slackening off. Pea-fed lambs command high prices in the Adelaide markets. In my opinion there is a greater return from them than anything. This part is more the home of the crossbred than the Merino; the latter very rarely does well, and if bred in the district is small-framed compared with the Merino grown in the northern areas. For scrub country I would not recommend anything but the Merino, on account of their being closer in the wool, which does not get torn and worn off like the open wool. For wool and mutton I advocate the Comeback. For breeding select first-cross ewes. They are better milk producers, and stand our cold wet climate better than the Merino. With these first-cross ewes mate the Lincoln ram. The ewes produced from the first-cross and the Lincoln ram are then mated to a Merino ram, thus producing the Comeback. This class will cut a heavy fleece of wool, which will range amongst the top prices in the market. The ewes are very much sought after for breeding purposes, and it is to be regretted that a line of 200 or 300 is difficult to obtain. The wethers are very heavy mutton sheep, and fatten quicker than either the Merino or Lincoln. Do not keep on breeding from the progeny too long, as they get too much on the Merino side, which results in smaller frames. Sell out occasionally and start afresh. The rams should not be too old, but vigorous. They leave their mark on many: the ewe is of great consequence, but the ram greater still, and thus with the sire is not the place to economise. Lambs should be tailed at about three weeks old. If they are allowed to get too old the loss of blood is greater, and the lamb takes longer to recover. Ewes and lambs should be driven as quietly as possible to the yards, in order not to get the latter overheated. Clean instruments should be used, and it is a great mistake to let the lambs go into a dirty yard after the operation. Trouble with blood poisoning will be encountered if this is done. Ewes should always be breeched before the winter, to obviate the fly pest. This will also mean less trouble with skirting at shearing time. Every sheepowner should dip his flock once a year: sheep infested with lice and tick will never do well, and the wool has a dirty, discolored appearance. In dealing with Merino wools there are three factors to be taken into account—first, the quality of the wool by which the value is arrived at. This factor, or quality, will be represented largely by the size of the sheep. Second, the length and strength of the staple which determines to what use the wool may be put, *i.e.*, whether combings or clothing. Third, the amount of 'conditions' or the quantity of urine matter the wool will lose in scouring. This may be considered the most important part in connection with the classing of Merino flocks, for the simple reason, although the Merino breed has many varieties, those grown in the one locality will be more regular in type, therefore the quality of the wool does not play the same important part. It may, however, be noted that, regular as these type of sheep are in the flocks, those of the more robust constitution and bigger frame are somewhat coarser in quality than the bulk. Therefore in classing small Merino flocks of from 1,000 up, a distinction of quality is required. The basis of the work otherwise should be conducted upon the principle of 'condition.' Crossbred wools should be graded according to quality from 36's (which generally is represented by a Lincoln) up to 50's, the first count in crossbred Merino there is to be attained. There are counts as follows, representing as different kind of breeds. From a wool's standpoint, Lincoln is preferred to all other long-woolled breeds, owing to its possessing a longer staple in its fleece. Lincoln, also, when used for crossing purposes, will yield a heavier fleece, and one which will maintain its weight longer. It also possesses greater lustre, which is an important factor with crossbred wool of coarser description. Any crossbred wool up to 46's count should have good lustre. The Leicester has been largely used for producing crossbred wools from the Merino. It has been favored chiefly owing to early maturing qualities, and when mutton is required has a shapely carcass, but owing to the finer quality in wool than the Lincoln, has a shorter staple of fleece. Skirting is an important part in the preparation of wool for market, and should be done carefully. After the shearer has taken off the fleece, it is gathered up by taking each hindquarter and drawing it towards the body, and is then thrown out on a table tips uppermost. The table should be large enough to enable the skirter to spread the fleece out sufficiently for him to see clearly what he is doing. After the skirting is finished he should fold in the two sides and roll from both ends, thus having the shoulder wool on the outside of the fleece, which gives it an attractive appearance. Where flocks number under 300 sheep the skirting should be very light, taking off only the stained pieces and locks. Perhaps in this case the bellies may remain on the fleece. Where there are from 500 up to 1,000 sheep the skirting can be a little heavier, by taking off the lower trimmings and the short matted piece around the head, also any burry and seedy pieces. In this case pack the bellies separately from fleece wool. With 1,000 and over the skirting may again be a little deeper, and deep breech parts from hindquarters should be removed. These sections should again be sorted by removing lower trimmings. This will give two lines—first pieces and second pieces. The hairy sections down the breast may be removed; these should be put with the breech and branded first pieces. The two principle grades of wool are separated under two distinct headings—Merino and crossbred. All wools that range below 58's quality come under the term of crossbreds. Merino wools range upwards from 60's quality, and 58's is spoken of as bare 60's. Crossbred wools are graded into three different qualities—fine crossbred, which starts at 50's to 56's qualities: medium crossbred, from 44's to 50's qualities; coarse crossbred, 36's to 44's qualities. If the wool is classed under these different terms the woolbuyers have confidence in valuing it, thus better prices may be secured. Small flocks of under 300 sheep cannot be classed to any great extent, but care should be taken to get the wool up to the best advantage. The only classing practicable is to keep out any ragged or discolored fleeces, and keep Merino separate from crossbred. Where flocks number from 500 to 1,000 the classing can be carried out to better advantage. If the flock is mixed there will probably not be sufficient Merinos to make more than one class, but if it is necessary make three classes of crossbred—super crossbred, medium crossbred, and Lincoln. Keep out any heavy conditioned, matted, or broken fleeces. Rams' wool should be kept separate. These can be packed into bags, or put on top of some part bale and marked. In classing Merino flocks of from 1,000 to 2,000, three classes are recommended for fleece wool; these should be divided as follows:—A.A., the brightest, most attractive fleeces, having good regular length, and staple sound. A., those fleeces a little shorter, more irregular in length, and heavier in condition. C.C., the very short fatty, and heaviest

conditioned fleeces of all, usually found to have a black tip. Brand the bales neatly with stencil plates, the name of the property, the class of wool, and number the bales from one upwards. Brand on the flap end, and also on the seam side of the bale."

Longwood, October 11.

(Average annual rainfall, 37in. to 38in.)

PRESENT.—Messrs. Hughes (chair), J. Brown, E. Colley, H. Winter, J. C. Blakley, F. Hill, E. J. Oinn, E. A. Glyde, A. F. Furniss, J. R. Coles (Hon. Sec.), and two visitors.

DRAINAGE.—A paper on this subject was read by Mr. E. J. Oinn. He had been most successful in draining a peaty flat running down the centre of a gully, the sides being of a fine sandy loam nature, by cutting an open drain 18in. deep down one side with three or four similar drains diagonally across the gully towards the top. In these, lines of slabs, 6in. wide and 1½in. thick, were placed parallel to each other, about 4in, apart, with others, 9in. wide and 1½in. thick, placed along the top. This formed a culvert, 6in high by about 4in. wide. He had tried drains with a small stone culvert at the bottom, and a layer of rough stones on top, which silted up within 12 months; underground drains with straight saplings and bushes (which lasted for some time in land with a clay subsoil, but which were useless in sandy land) and other schemes. They were all unsuccessful, with the exception of the first-mentioned. In fairly flat country it was a good idea to plough the fields in 16ft. wide lands, separating each by a double-depth furrow. Drains in an orchard should run across the slope. Members thought 3ft. and 4ft. a better depth for drains. Where the surface consisted of fine sand it might be wise to place stones in the bottom of the drains, on these pipes, stones, brush or bushes, and then fill in the soil. Where stones were plentiful, they could be well got out of the way in this manner. Pipes were preferred by some, as they were easy to handle, involved less labor, and less difficulty was experienced in locating any stoppage that might occur. Mr. Oinn thought pipes unserviceable unless perforated.

Myponga, October 8.

PRESENT.—Messrs. G. Hunt (chair), G. Maslin, K. Stephenson, F. Pengilly, M. McGuinness, E. Everard, J. Müller, F. Müller (Hon. Sec.), and three visitors.

DRY BIBLE AND RICKETS IN DAIRY COWS.—The Chairman read a paper on this subject. The symptoms of dry bible in young cattle consisted of a cramped appearance of the chest and sides, and the ears drooping forward. If very bad the beast seldom lay down, and there was a tendency to chew bones, sticks, or leather. The first indication of the trouble in cows was a sudden cessation of the milk flow. Dryness of the nose, with rapid heartbeats, sometimes as high as 80 to the minute was also noticeable. The normal heartbeat was 47 or 48 per minute. The treatment advised was one bottle of linseed oil, in extreme cases, ¼lb. of carbonate of soda, one handful of salt in ½gall. of flour water, mixed well. With this the animal should be drenched every three of four hours. The flour water had the effect of softening the impaction, and he had given an animal as much as 5galls. of this in 48 hours without causing trouble. Cows on recovery showed a big increase in milk flow. Shortage of herbage was responsible for the trouble. With the promise of a dry season, it was advisable to grow maize, sorghum, or mangolds. In the case of rickets, the beast showed signs of stiffness, went down, appeared cramped in the back, as well as stiff in the joints. The trouble was due to the feed being too fresh or sloppy, or without substance. The animal should be drenched with salt and bonemeal, or moved to salt country. Members agreed that salt and bonemeal would prevent rickets, but considered them hardly suitable for a drench. Yacca poisoning was generally considered incurable when in the advanced stages.

Port Elliot, October 13.

(Average annual rainfall, 20·33in.)

PRESENT.—Messrs. J. Brown (chair), H. B. Welch, J. F. Vince, J. D. Gordon, H. Welch, J. Chibnall, H. Green, and W. E. Hargreaves (Hon. Sec.).

GRASSES AND FODDERS.—Some members thought Cape oats would do better and return more feed than grasses. They spoke well of prairie grass, but the stock ate it out by the roots. *Phalaris commutata* was one of the best grasses. It would grow through the winter on poor soil and would make good hay; it would also stand feeding down.

Potatoes.—Members recommended green manuring with oats or barley land intended for potatoes. They were divided in opinion as to whether it was advisable to apply manure before or at the time of planting the sets.

Rabbit Destruction.—Mr. J. D. Gordon had been very successful in destroying rabbits by ploughing furrows about 3in. deep and from 4in. to 6in. wide. Into these for two nights he placed apples for free feeding. Baits were then prepared by cutting apples into pieces an inch square, placing a layer of these in an old kerosine tin and dusting them with strychnine from an old pepper pot. On the third night the baits which needed to be fresh were placed in the furrow. It was advisable to have the paddocks clear of stock whilst poisoning, and all untouched baits and dead rabbits should be buried. He had picked up as many as 409 rabbits as the result of one night's poisoning in this way.

SOUTH-EAST DISTRICT

Keith, October 11.

(Average annual rainfall, 19·20in.)

Present.—Messrs. MacIntyre (chair), Makin, Redpath, Shannon, Morcom, and Lock (Hon. Sec.).

The Agricultural Bureau.—Mr. J. A. Lock read a paper, in which he said that the Agricultural Bureau had done a great deal to advance agriculture and horticulture in South Australia. The expressions of opinions and the exchanges of thought and experience at these meetings had done much in this direction. He expressed the view that the Government should make provision at Port Adelaide to enable any farmer so desiring to forward his wheat to that port to be shipped in bulk. Bags could then be returned to him and used for two or three seasons. The Bureau could urge on the Government the necessity for action in this regard. When a member took up residence in another district, it was advisable for him to transfer his membership to the Branch there, and thus secure the benefit of the experience of local farmers.

Kybybolite, September 30.

(Average annual rainfall, 22in.)

Present.—Messrs. A. Bradley (chair), W. J. Colebatch, B.Sc. (Agl.), M.R.C.V.S., H. Lacey, G. H. Hahn, P. Anderson, C. Hahn, A. Bradley, jun., E. W. Duffield, H. B. Schinckel, and E. C. Schinckel (Hon. Sec.)

Shearing.—Mr. H. B. Schinckel read a paper, from which the following is taken:—"The owner of a small flock, say some 300 or 400 sheep, would find it beneficial to have a shed, even if it does not contain all the modern conveniences of an up-to-date woolshed, through which he may shear his sheep under personal supervision. Most farmers have a machinery-shed, and without going to any very great expense a portion of this may be utilised for shearing. This, of course, may necessitate the removal of some of the implements, but as the shearing will probably last not longer than a week or so this short time will not be detrimental to those which are constructed principally of ironwork. A small section of grating may be put down temporarily to accommodate 30 or 40 sheep overnight, and with room for a shearing-board, which may also be temporary, table, and two or three bins, a space of about 20ft. square only is required. Hand-shearing is generally admitted to be the less severe on the sheep, both during the operation and after being put out in the paddock in extremely hot or cold weather. Furthermore, this method is much less costly, as all expenses, both primary and those incurred during shearing, are borne by the shearer; whereas with machines the cost of installing and upkeep is a pretty big item. Some time ago 6,000 sheep were shorn, 3,000 with shears and 3,000 with machines, and kept under exactly similar conditions. This was done for three years, and at the end of the term the hand-shorn sheep showed an increased clip of 1½lbs. per head. Probably the greatest points in favor of the machine are those of a quicker shearing and the obviation of the increasing difficulty of procuring hand-shearers. In a pen of machine-shorn sheep one invariably finds a big percentage of them badly pricked and cut, but with a capable man, who has a thorough knowledge of his machine, these painful scars need not be prevalent. It is contended by a great many small flock-owners that classing is not worth the candle, but this is a fabulous contention founded on a few lucky sales of some unprepared clips in the open market. I do not for one moment urge that the owner of a few hundred sheep should get his wool up into four or five classes unless, of course, he has that many distinct types of sheep, which at any time is a very unprofitable flock to have; but it is advisable, and I hope practicable with most of us, to make a line of four bales, showing uniformity in quality, character, and staple. If one has a few fleeces of other types of wool, keep them all separate, even if it is necessary to press them in the same bale to fill it, but acquaint the brokers of it. They will make a note in the buyer's catalogue, and he may then inspect and buy with confidence. As is the case in the preparation of all produce it is advisable to cater for the buyer."

Tintinara.

(Average annual rainfall, 18·78in.)

PRESENT.—Messrs. R. J. Gully (chair), J. Donaldson, Bell (3), Stead (2), J. E. Taylor, Kneale (2), R. K. Henderson, A. Koeppen Wendt, Baniger (2), C. M. Ives, C. P. Hodge, M. F. Hodge (Hon. Sec.).

FRUIT CULTURE.—The Horticultural Instructor (Mr. Geo. Quinn) delivered an address:—When setting out with the idea of planting an orchard in a new district, he said, one should try different varieties of fruits in the home garden first. This would give a very good idea in a few years what varieties of trees would do best and give the best commercial result. The position of the house very often governed the site for the garden, and as a high site was usually selected for the house, this, unless the rainfall was plentiful, was not a suitable place for a fruit garden. Taking this district as an instance, where the rainfall was about 20in., he suggested that they should choose the lowest ground for the orchard. They should examine this soil in February and March to see whether it contained sufficient moisture to carry the fruit tree through the summer. In average districts moisture was not more important than shelter, either natural or artificial. Where they were without good natural shelter for their fruit trees they would find it necessary to provide shelter. He suggested Tamarisk as the best and quickest growing for sandy soil. They should be planted early and closely together to provide a dense breakwind. The Aleppo Pine also made a good shelter, but he suggested growing them from seed or in plots during the first season so that they could be set out earlier than if procured from the Forest Department. This pine did much better if set out earlier in the season, say April and May, with the first rains. *Pinus insignis* would also thrive well and should hold out in this locality. The Upright Poplar (Lombardy poplar) should also do well. In Port Adelaide district right on the white sand this tree was doing remarkably well. The trees should be planted closely together. He strongly advocated planting trees around the house, and where there was natural timber scattered about he advised filling in as much as possible. He obtained the best results from Tamarisk, putting in cuttings 12in. to 18in. long and leaving about 1in. out of the ground. It did well in sand and thrived on a limited amount of moisture The orchard should be netted in with 1¼in. mesh netting before the trees were planted, otherwise the rabbits would ringbark them. Preparation of the soil was more important at the outset than when dealing with the land for a wheat crop. It was necessary to break the ground as deeply as possible, keeping the top soil in its natural position without inverting the clay. This could be done either with the disc plough or the subsoiler. The soil with the clay close in this district would eventually give the best results. The whole of the area to be planted should be ploughed 12 months ahead and cleaned free of all roots. Native plants were attacked by fungi which would transfer themselves to the fruit trees, as had happened on new land at Crafers. He had tried growing trees in pots, and planted them out early in the season, and found that by doing so they made a fine supply of roots. When planted in midwinter the roots remained dormant, and if a dry summer were experienced the trees might have a very hard struggle to get through. When planted later the tree started to make root at the same time that it came into bud, and therefore the top soon received a check. He therefore advised planting while the ground was still warm, so that the roots started growing before the top of the tree. It was the usual practice to plant the trees to the same depth as they were in the nursery, with the exception of citrus trees, as raising or lowering a deciduous tree 1in. would not make any difference to its growth. The hole for the tree should be 2ft.

quare at the top, with the sides sloping outwards. The top portion of the soil should be taken out with the spade and the bottom barred or forked up well, leaving it nice and loose. Each vine or tree should have a cup full of bonedust. It was much better to make the hole fit the roots than the roots to fit the hole. They should be spread well out in the hole. When putting the soil on to the roots do not put any fermentable matter on top of them. Cover them well with fine soil and hold the tree upright and compact the soil around the roots with the feet, then fill in the hole to a level with the surface. There were three systems of planting—Square, rectangular, and septuple. He advised the square system. They could then work the land at right angles and thus keep it well worked down. When planting young trees they should give attention to their immediate surroundings and dig 6ft. square around each. When taken from the nursery the roots were probably cut straight off so that it became necessary as the roots were curtailed to do the same with the top. It was also advisable to shape the trees. Trees taken from the nursery should represent one year's growth. They should be cut right back to the height of stem required, the laterals being cut back to the base buds. An evenly balanced tree was secured by, in the summer, just nipping the top out of the strong growing shoots to help the weaker shoots. Any pruning done in the winter time tended to cause increased wood and leaf growth. When done in the summer it tended to produce fruit-bearing small wood. In the northern part of this State, where the soil was heavier, the best results had been obtained by breaking up the land deeply in the early winter, ploughing away from the trees, and in the spring ploughing back to the trees to a shallow depth. In wet districts it was best to plough once and then put the scarifiers through and keep the orchard clean. Where matured trees were over vigorous and not fruiting well they should be given less tillage and practically no winter pruning. The pests of the fruit tree were confined to the insect family and fungi. The insects were divided into two families—suckers and chewers. The former were got rid of by spraying over them kerosine wash, tobacco, &c.; the chewing or gnawing section by poisoning their food with arsenate of lead or other poisons. The fungus pests were either external or internal in their occurrence on the host plant. The external kinds might be destroyed when their presence was seen by using dustings of sulphur or copper sprays. Those entering the tissues must be treated in a preventive fashion before their ravages were visible. This usually took the form of spraying the trees with Bordeaux mixture or other copper compounds just as the flower buds were opening.

Wirrega, October 4.

(Average annual rainfall, 19in. to 20in.)

Present.—Messrs. H. Exton (chair), F. and L. Densley, C. and F. Meier, J. Green, L. Pitman, W. Fairweather, R. Williams, and L. Cook (Hon. Sec.).

Disc and Mouldboard Ploughs.—In a paper on this subject Mr. L. Densley said that for use in new mallee country where there were numerous stumps and shoots, and the soil had a tendency to sourness, he preferred the mouldboard plough. There was generally a difficulty in securing sufficient stubble to carry a fire, however, and there the disc implement was very useful. It turned the stubble nicely under and did not foul so much as the mouldboard. It was lighter on the horses, and whilst it did not pull out so many stumps as the mouldboard implement, it did excellent work among broom roots, especially if the latter had been through the ground previously. The expenditure on repairs, however, was comparatively heavy. It left the sandy soil, which was very sour, too smooth for fallow. The mouldboard left it rougher, and consequently a greater surface was exposed to the sun and air. It also pulled out a great many stumps and weakened those that remained. The disc cultivator did good work in destroying shoots at seeding time.

Minister of Agriculture.

POINTS FOR PRODUCERS.

Kybybolite Experimental Farm.

Farmers' Day at Kybybolite Farm, in view of the many problems being worked out by Mr. Colebatch (Superintendent of Agriculture in the South-East), is an event which is always looked forward to by agriculturists in that and surrounding districts. At the invitation of the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) about 130 members of the Bureau and a number of visitors attended this year's inspection of the farm, which was held on Friday, November 21st. In addition to the Minister, those present included the Hon. J. Cowan, M.L.C., Mr. Bodey, M.P., Representatives Livingston (South Australia) and Stumm (Queensland), Messrs. G. R. Laffer and F. Coleman (of the Advisory Board of Agriculture), and the Secretary to the Minister (Mr. W. L. Summers). With his usual forethought, Mr. Colebatch had distributed printed pamphlets setting out briefly the principal features of the work carried out during the 12 months, and this proved of great advantage to the visitors, who spent an interesting time inspecting the crops, stock, buildings, &c. During the day a convincing demonstration of the value of explosives in removing large timber was given. A heavy charge of rendrock was inserted (in seven holes) beneath an immense red gum, which had a diameter of 5ft. at the base. The explosive, which was fired with electricity, completely lifted the tree out of the ground. It was considered that the removal of the tree in the ordinary way would have taken two men a couple of days. At the conclusion of the inspection a number of speeches were delivered, the Minister and others expressing their high appreciation of the enthusiasm of Mr. Colebatch and his assistants, and of the value of the work being done at the farm.

Show of S.A. Produce in England.

Writing with reference to the display of South Australian produce at the London Grocers' Exhibition, which was held at Islington from September 20th to September 27th inclusive, the Trade Commissioner states :—" In addition to the ordinary daily papers, the South Australian exhibit received the special attention of practically all the trade papers of any note in the United Kingdom. The following is an extract from *The Grocer* (one of the leading organs of the grocery trade), and the other papers are practically all of the same opinion in regard to the South Australian exhibit :—' Of the number of colonial displays in the exhibition that of the South Australian Government was undoubtedly the most comprehensive and practical, and great credit is due to Major A. E. M. Norton, the Trade Commissioner for

South Australia, who was responsible for the exhibit. Among the produce shown was an excellent range of wines, including the following brands of burgundies :—Tintara, Harvest, Emu, Keystone, Orion, and Victoria. A splendid assortment of dried and bottled fruits was on view, and our attention was drawn to samples of new season's currants, which have arrived in the pink of condition. South Australian honey in glass jars bulked very largely in the display. It is a pure product, and each jar bears a Government label with a guarantee of purity. Tomato sauce, tinned meats, eucalyptus oil, wheat, and other products of the colony went to make up an attractive exhibit ; nor must we omit reference to the fresh apples and pears on show, which are of excellent appearance and quality, and the sale of which is steadily increasing. The exhibit was a real live display, as everything that was shown can be obtained from those wholesale houses who have taken up agencies for the sale of South Australian products.' "

Action of Lime.

It is said that farmers as a class are rather neglecting the use of lime ; they are depending too much on chemical manures, and omitting to give the soil dressings of such a necessary constituent as lime. If so, this is a matter of regret, because the crops will suffer in health and quality. Some chemical manures, such as sulphate of ammonia and kainit, use up the lime in the soil, and all fertilisers, by increasing the crop, increase also the consumption of lime. It is, therefore, the part of a good farmer to see that the soil of his farm is well supplied. The action of lime hastens the decay of vegetable matter and sweetens sour lands which may have been more or less submerged. It increases the capillary condition of soil, prevents fungoid diseases, and promotes the growth of more nutritive herbage in pastures ; it also decomposes minerals in the soil containing potash and other food constituents, and renders them available for the needs of the plants. Further, it decomposes organic matter and promotes the important process which is so much in evidence at present—" nitrification." Thus, to sum up, lime may be said to have a mechanical, chemical, and biological action, and the importance of a systematic application of this invaluable soil improver and fertiliser to lands which are at present in lack of it should be apparent to all agriculturists. When this need is supplied, many of the ailments from which stock suffer, and often caused from lack of this very necessary substance in plant food, will be avoided. Acidity of the stomach, so frequently met with amongst cattle, is attributable to want of alkaline matter in the food supply. Malformations at birth, particularly with foals and lambs, can also be traced to the same cause. The anæmic condition, often noticeable amongst cattle which have been pastured for any lengthened period on light country, has the same origin.—*Mark Lane Express.*

Victorian Harvest.

According to a telegram appearing in the press, the Victorian Railway Commissioners estimate the coming wheat harvest of that State at 37,000,000bush. The 1910-11 harvest, which was a record, totalled 34,000,000bush.

Potatoes as a Food for Pigs.

These experiments were designed to test the value of potatoes as compared with maize as the principal food in the rations fed to pigs. The basal ration was fixed and the animals given as much potatoes and maize as they would eat. The 43 pigs used were of the improved German breed, about 44lbs. in weight and 12 weeks old, the object being to fatten them to a slaughter weight of about 240lbs. in five months. The amounts of food consumed, the increases in live weight, and the profit in 22 weeks will be seen from the following table :—

	Lot 1 (11 Pigs) Average per Pig.	Lot 2 (11 Pigs) Average per Pig.	Lot 3 (11 Pigs) Average per Pig.	Lot 4 (10 Pigs) Average per Pig.
	lbs.	lbs.	lbs.	lbs.
Foods consumed—				
Fishmeal	25½	25½	25½	25½
Gram	335	335	335	335
Rye chaff	—	—	10½	80
Meatmeal	—	—	—	19
Maize	377	—	—	—
Potatoes	—	1,479	1,581	1,389
Increase in live weight	187	168	188	189
Profit (*i.e.*, value of increase less cost of food consumed)	27s. 11d.	24s. 1d.	31s. 3d.	32s.

The value of the increased live weight was reckoned at 5·4d. per lb., and the costs of the foods as follows (per lb.) :—Maize, 0·9d. ; gram, 1d. ; fishmeal, 1·4d. ; meatmeal, 1·7d. ; rye chaff, 0·1d. ; and potatoes, 0·18d.—*Journal of Board of Agriculture.*

◆

New Views on Feeding Livestock.

In the past few years views as to the fattening of livestock have been changing, and the opinion has gained ground that too much importance has been and can be attached to the nitrogenous part of the ration. There is a danger, perhaps, that too much weight may now be attached to starchy foods as the pendulum slowly swings round, as it is in this direction that we are now told lies economy and wisdom. Certainly a perusal of the results of the many feeding experiments which have been conducted for many years past suggests that the importance of nitrogenous food as against starchy has been over-estimated, and that the pockets of farmers have suffered in consequence. Many figures, in fact, show good results from a much wider albuminoid ratio than was formerly allowed to be necessary, as good in some cases as much narrower ones, and this must mean, as a rule, less expenditure in food. A most significant point in this connection is the high value which is now found to lie in some kinds of mineral manuring as compared with manure produced by expensive feeding, the latter being formerly supposed to be a more important set-off to the expense of feeding than is now known to be the case. If 1lb. of protein will fatten stock as well as double this amount, there is little sense, surely, in buying the larger quantity at present high prices, whatever the value of the manure; and yet this is what some farmers still persist in doing. But the question is not nearly so simple as it seems, and our knowledge is as yet so imperfect, owing to absence of research on feeding-stuffs, that feeding by rule is not a safe guide, and practical men are sometimes nearer the mark than their scientific advisers.—*Livestock Journal.*

Encouraging the Farmer.

A progressive West Virginia breeder, says *The American Agriculturist*, has offered eight Ayrshire bull calves as prizes to farmers of Ohio and Brooks counties; two each for the erection of the first two silos, the best acres of alfalfa, the best year's record of milk and butter-fat tests, and the best prepared record of farm accounting. Here is a progressive idea which shows also abundant faith in farming. Surely it will have a good effect in its locality. Why not adopt it, or a modification of it, in other sections?

Cows Holding up Milk.

It is quite common to find cows that have the bad habit of holding up their milk—a thing that is hard to overcome unless a person knows just how to go about it. There is always a definite reason for it, however, as a cow that has everything to please her physically and mentally will be very unlikely to hold up her milk, and a cow that holds up her milk and is put in physical and mental comfort will quite probably give it down again. *Farm and Home* (England) discusses this subject briefly in a way that gives some interesting pointers to persons dairying anywhere, and says—"Cows are often 'difficult' in regard to giving down their milk perfectly in the height of the milking season. They fall into the habit in the flush of feed from tenderness of the udder, especially if the spaces between milkings are unequal, so that at one of them the bag becomes very much overstrained and painful. The bag thus becomes inflamed, swollen, and hard, and withholding the milk or any part of it tends to increase the difficulty. From an unequal division of time between milking, some cows habitually hold up their milk at night and give it down in the morning. The habit once being formed there is no sure cure for it. The same treatment will not work alike on different cows. As a rule, cows give down best in a few minutes after they first come into the stable or yard without having any food before them or anything to attract attention or disturb them, but some will give their milk more freely if eating something that they relish well, so that their attention is more taken up with the food than the milking. Regular, evenly timed, quick, quiet, and comfortable milking is essential, and the best means both for preventing and for breaking up the bad habit in cows of holding up their milk."

Coconut Fat for Rearing Calves.

In the *Bulletin of Agricultural Intelligence and Plant Diseases*, February 1913, results are given by Dr. Paul Schupple of experiments carried out for eight years in which coconut fat was used as a substitute in rearing calves for butter-fat. This substance contains 99 per cent. of pure fat, and is the cheapest vegetable fat obtainable. The fat and skim milk were used in the proprotion of 35 grains of fat to 1 litre of milk (5½ozs. to the gallon), heated to 60°C. and passed through an emulsion drum. A milk containing 3½ per cent. of fat was thus obtained at a cost of 4½d. per gallon. For satisfactory results the milk must be made fresh each time. It was found that calves could be reared much more economically on emulsion milk than on a mixture of whole and skim milk, and that there was no difference in the final weight of calves reared according to these two systems.

Imports and Export of Fruits, Plants, Etc.

During the month of November, 1913, 2,838bush. of fresh fruits, 10,420bush. of bananas, 2,904 bags of potatoes, 566 bags of onions, and 38pkgs. of trees, plants, bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910; 2pkgs. of plants and 176bush. of bananas were destroyed (over-ripe). Under the Federal Commerce Act, 314 cases of fresh fruits, 400pkgs. of honey, 651pkgs. of dried fruit, 36pkgs. of preserved fruit, and 1pkg. of seeds were exported to oversea markets during the same period. These were distributed as follows:—For London, 400pkgs. of honey and 1pkg. of dried fruit; for Canada, 375pkgs. of dried fruit; for South Africa, 275pkgs. of dried fruit; for India and the East, 36pkgs. of preserved fruit; for Cyprus, 1pkg. of seeds; for New Zealand, 205 cases of oranges, 103 cases of lemons, and 6 cases of cherries. Under the Federal Quarantine Act, 8,645 cases of dates, 175pkgs. of dried figs, and 1,847pkgs. of plants, bulbs, seeds, nuts, &c., were examined and admitted from oversea markets.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"W. C.," Mount Compass, wants advice regarding a heifer which has irregular cud and appetite after calving, shivers and is stiff, weak, and tucked up, improves in a few days.

Reply—The symptoms point to inflammation of the womb. The advice you had to give nux vomica was sound, and if there is a repetition of the symptoms, 10 drops of the tincture, alternated with a similar quantity of tr. pulsatilla in a little water twice daily, will be followed by improvement.

The Morphett Vale Branch Agricultural Bureau, asks the earliest age advisable for castration of colts.

Reply—There is no objection to castration at a few weeks old, while sucking, when the testicles are in the purse ; however, it is more usual to operate on yearlings, when the glands are more developed.

HORTICULTURE.

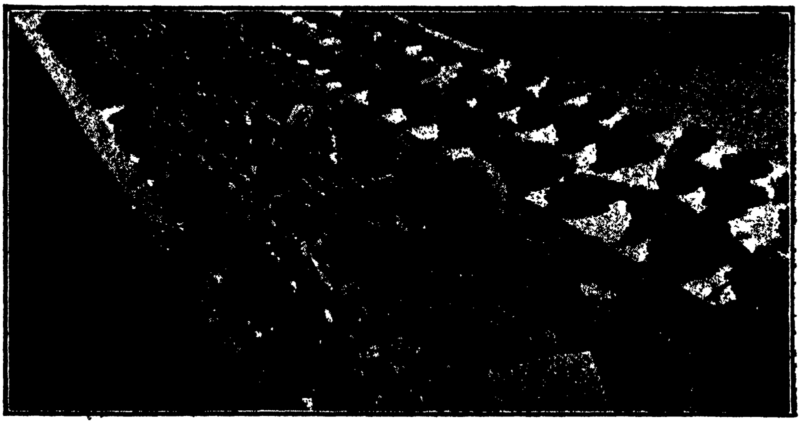
(Replies supplied by Mr. G. Quinn, Horticultural Expert.)

"A. C. I.," Port Pirie, has some orange and mulberry trees which are covered with small black ants. He asks if they affect the growth of the trees.

Reply—The continued presence of black ants on fruit trees is usually an indication that some suctorial insect—scale or aphis—is present upon it, giving rise to the sweet honey dew upon which the ants feed. It is possible this is so in your case, and you are advised to examine the twigs and bark closely for the presence of one, or perhaps both these pests. The aphides prefer the tender tips, the scales are usually found upon the leaves—often alongside the midribs—and upon the bark of the younger parts. The remedy is to spray the trees with kerosene emulsion or resin wash. If there is a sooty coating upon the leaves or twigs this is evidence of the presence or recent visitations of these insects.

"T. H. M.," Clare, forwards samples of twigs of currant and sultana vines which he believes are affected with anthracnose. He asks if his supposition is correct, and for advice as to treatment. Other correspondents have forwarded vine cuttings similarly affected.

Reply.—The disease attacking twigs of currant and vines is, as you surmise, the anthracnose, or black spot of the grapevine (*Sphaceloma ampelinum*, De Bary). The only remedy to my knowledge which proves a check upon this fungus after the leaves start is Bordeaux mixture, and I advise you to give the plants a thorough drenching with same at once; after which, if the season turns normal, you may yet secure a fair return of sound fruit and wood growth for next year. After pruning and promptly burning the prunings next winter, I advise you to swab the spurs and canes with a saturated solution of iron sulphate with sulphuric acid as follows:—50lbs. iron sulphate, 10galls. hot water, 1 pint sulphuric acid (commercial). Using a wooden vessel, pour the acid over the iron crystals, and then stir in the boiling water. This mixture will injure the clothing or the skin, so precautions should be taken to protect the face and hands. This remedy is relied upon in Europe and North America. If the summer continues to prove showery, I advise you keep the vines fairly open to sunlight, as allowing the foliage to dry rapidly is a great help in the suppression of the anthracnose and other fungus diseases. We have used Bordeaux mixture, prepared according to the Woburn formula, against curl leaf fungus with success, and it goes through the pump without any clogging of valves or nozzles.



Fruit Exhibit, Adelaide Show.

WHEAT PRODUCTION OF THE FUTURE.

THE WORLD'S NEED AND SUPPLY.

Of the many important questions now engaging the attention of scientists, there are few of more absorbing interest than that relating to the future wheat supply and requirements of the world. Since Sir William Crookes, in 1898, made his oft-quoted pronouncement, the contributions to this subject have been many and varied. One of the latest and most weighty is contained in the address delivered at the recent meeting at Birmingham of the British Association for the Advancement of Science by Professor H. N. Dickson, President of the Geographical Section. The address is printed *in extenso* in the October number of *Nature*, and from that journal the following extract is taken :—

In his presidential address (said Professor Dickson) to the British Association at its meeting at Bristol in 1898, Sir William Crookes gave some valuable estimates of the world's supply of wheat, which, as he pointed out, is "the most sustaining food-grain of the great Caucasian race." Founding upon these estimates, he made a forecast of the relations between the probable rates of increase of supply and demand, and concluded that "Should all the wheat-growing countries add to their (producing) area to the utmost capacity, on the most careful calculation the yield would give us only an addition of some 100,000,000 acres, supplying, at the average world-yield of 12·7bush. to the acre, 1,270,000,000bush., just enough to supply the increase of population among bread-eaters till the year 1931." The president then added, "Thirty years is but a day in the life of a nation. Those present who may attend the meeting of the British Association 30 years hence will judge how far my forecasts are justified."

Half the allotted span has now elapsed, and it may be useful to inquire how things are going. Fortunately this can be easily done, up to a certain point at any rate, by reference to a paper published recently by Dr. J. F. Unstead (*Geographical Journal*, August, 1913), in which comparisons are given for the decades 1881-90, 1891-1900, and 1901-10. Dr. Unstead shows that the total wheat harvest for the world may be estimated at 2,258 million bushels for the first of these periods, 2,575 millions for the second, and 3,233 millions for the third, increases of 14 per cent. and 25 per cent. respectively. He points out that the increases were due "mainly to an increased acreage," the areas being 192, 211, and 242 million acres, but also "to some extent (about 8 per cent.) to an increased average yield per acre, for while in the first two periods this was 12bush., in the third period it rose to 13bush. per acre."

If we take the period 1891-1900, as nearly corresponding to Sir William Crookes's initial date, we find that the succeeding period shows an increase of 658 million bushels, or about half the estimated increase required by 1931, and that attained chiefly by "increased acreage."

But signs are not wanting that increase in this way will not go on indefinitely. We note (also from Dr. Unstead's paper) that in the two later periods the percentage of total wheat produced which was exported from the United States fell from 32 to 19, the yield per acre showing an increase meanwhile to 14bush. In the Russian Empire the percentage fell from 26 to 23, and only in the youngest of the new countries—Canada, Australia, the Argentine—do we find large proportional increases. Again, it is significant that in the United Kingdom, which is, and always has been, the most sensitive of all wheat-producing countries to variations in the floating supply, the *rate* of falling-off of home production shows marked if irregular diminution.

Looking at it in another way, we find (still from Dr. Unstead's figures) that the total amount sent out by the great exporting countries averaged, in 1881-90, 295 million bushels; 1891-1900, 402 millions; 1901-10, 532 millions. These quantities represent respectively 13·0, 15·6, and 16·1 per cent. of the total production, and it would appear that the percentage available for export from these regions is, for the time at least, approaching its limit, *i.e.*, that only about one-sixth of the wheat produced is available from surpluses in the regions of production for making good deficiencies elsewhere.

There is, on the other hand, abundant evidence that improved agriculture is beginning to raise the yield per acre over a large part of the producing area. Between the periods 1881-90 and 1901-10 the average in the United States rose from 12bush. to 14bush.; in Russia from 8bush. to 10bush.; in Australia from 8bush. to 10bush. It is likely that, in these last two cases at least, a part of the increase is due merely to more active occupation of fresh lands as well as to use of more suitable varieties of seed, and the effect of improvements in methods of cultivation alone is more apparent in the older countries. During the same period the average yield increased in the United Kingdom from 28bush. to 32bush., in France from 17bush. to 20bush., Holland 27bush. to 33bush., Belgium 30bush. to 35bush., and it is most marked in the German Empire, for which the figures are 19bush. and 29bush.

In another important paper (*Geographical Journal*, April and May, 1912) Dr. Unstead has shown that the production of wheat in North America may still, in all likelihood, be very largely increased by merely increasing the area under cultivation, and the reasoning by which he justifies this conclusion certainly holds good over large districts elsewhere. It is of course impossible, in the present crude state of our knowledge of our own planet, to form any accurate estimate of the area which may, by the use of suitable seeds or otherwise, become available for extensive cultivation. But I think it is clear that the available proportion of the total supply from "extensive" sources has reached, or almost reached, its maximum, and that we must depend more and more upon intensive farming, with its greater demands for labor.

The average total area under wheat is estimated by Dr. Unstead as 192 million acres for 1881-90, 211 million acres for 1891-1900, and 242 million acres for 1901-10. Making the guess, for we can make nothing better, that this area may be increased to 300 million acres, and that under ordinary agriculture the average yield may eventually be increased to 20bush. over the whole, we get an average harvest of 6,000 million bushels of wheat. The average wheat-eater consumes, according to Sir William Crookes's figures, about 4½bush. per annum; but the amount tends to increase. It is as much (according to Dr. Unstead) as 6bush. in the United Kingdom and 8bush. in France. Let us take the British figure, and it appears that on a liberal estimate the earth may in the end be able to feed permanently 1,000 million wheat-eaters. If prophecies based on population statistics are trustworthy, the crisis will be upon us before the end of this century. After that we must either depend upon some substitute to reduce the consumption per head of the staple foodstuff, or we must take to intensive farming of the most strenuous sort, absorbing enormous quantities of labor and introducing, sooner or later, serious difficulties connected with plant-food. We leave the possibility of diminishing the rate of increase in the number of bread-eaters out of account for the moment.

We gather, then, that the estimates formed in 1898 are in the main correct, and the wheat problem must become one of urgency at no distant date, although actual shortage of food is a long way off. What is of more immediate significance to the geographer is the element of change, of return to earlier conditions, which is emerging even at the present time. If we admit, as I think we must do, that the days of increase of extensive farming on new land are drawing to a close, then we admit that the assignment of special areas for the production of the food supply of other distant areas is also coming to its end. The opening up of such areas, in which a sparse population produces food in quantities largely in excess of its own needs, has been the characteristic of our time, but it must give place to a more uniform distribution of things, tending always to the condition of a moderately dense population, more uniformly distributed over large areas, capable of providing the increased labor necessary for the higher type of cultivation, and self-supporting in respect of grain-food at least. We observe in passing that the colonial system of our time only became possible on the large scale with the invention of the steam locomotive, and that the introduction of railway systems in the appropriate regions, and the first tapping of nearly all such regions on the globe, has taken less than a century.

VINEYARD AND ORCHARD LAND.

THE USE OF EXPLOSIVES.

By H. E. Laffer, Lecturer in Viticulture and Fruit Culture, Roseworthy Agricultural College.

Much has been heard recently of the efficacy of explosives for the purpose of subsoiling, and, although a considerable amount of work has been done in this connection, there can be no doubt that much has yet to be learned before the practice becomes general. Take, for instance, vineyard lands, where the thorough breaking of the subsoil is of such vital importance to the welfare of the vines. We have on the one hand to refer to new vineyards in the course of planting, and on the other to the improvement of conditions in those vineyards or orchards which have been established for some years.

It must be admitted that throughout Australia the preparation of our vineyard or orchard lands prior to planting has in the past left much to be desired, and it is now a question as to whether these soils can be profitably and effectively treated to remedy the defects of insufficient preparation.

New Land.

In the first case I doubt if the subsoiling with explosives can be so effectively or economically carried out as it can be with teams and ordinary implements used for the purpose. That is to say, by usual subsoiling practices a more uniform broken layer of soil will be obtained to a depth of 18in. to 24in., according to the strength of implements and teams. Such a preparation, and one which appears to be essential in a great deal of our vineyard areas, may at a glance seem unnecessarily costly, and may be put down at £4 to £6 per acre. It must be remembered, however, that the average life of a vineyard may be taken as from 35 to 40 years, and therefore, in comparison with the increased vigor and yields distributed over this period, the cost may be looked upon as comparatively small.

The necessity for such a preparation, as well as the cost and the completeness with which it can be carried out, depends very largely upon the nature of the soil under consideration. Also it must be remembered that those soils most expensive to subsoil are the ones most needing the treatment. In loose, open, gravelly, or alluvial soils, costly subsoiling can be dispensed with, as the roots experience no difficulty in penetrating deep into the lower layers. Then there is the type of land with a surface crust—may be of clay or limestone—in which it becomes necessary to break this crust by a comparatively shallow subsoiling. Finally, there is the hard tough soil which needs thorough breaking for a depth of 18in. to 24in. In carrying out the work one has the usual implements, consisting of an ordinary strong single-furrow plough, which can be worked to a depth of 12in. or more, and, in addition, the goose-necked American subsoiler to follow behind the plough. The disadvantage of this system is that it tends to break the subsoil into ridges, and thus a second working at right angles to the first is an additional advantage.

A USEFUL IMPLEMENT.

For a more general working, and one which dispenses with the necessity of two implements, there is a plough little known in South Australia. This is the English ditching plough, which is designed to cut a furrow 20in. deep and 20in. wide. I have worked this implement, cutting a furrow 16in. wide and 20in. deep, and for soil not too stiff, consider it more economical than the combined plough and subsoiler. It is certainly quicker, and has the advantage of creating a more uniform mass of loose soil. Owing to its construction it is free from the objection of bringing the clay to the surface, and the greater the depth in proportion to the width of furrow the less does this objection become.

To work the plough to this depth will need a team of eight good horses; but that is no more than it would take to do similar work with the subsoiler and plough. In any case, whatever system is adopted, the result of subsoiling is to create a depth of broken soil into which the young roots easily spread and which absorbs and retains a large quantity of moisture.

Now to compare this treatment with similar work done by explosives.

To anyone who has observed the effect of explosives on a soil, it would appear that, though one may get a deeper preparation, it cannot be so even in its nature as that done by the plough and subsoiler. To a great extent the soil is broken in a more or less local position around the seat of the charge or shot. The efficiency of the work done by explosives is entirely dependent upon the physical condition of the soil at the time of operation; for, unless it is comparatively dry and readily broken into fragments, the effect of the explosion is to drive it into an even more compact condition, with an almost water-tight cavity at the bottom. Even assuming that the soil is in a condition to give the best results, if anything like uniformity of preparation is to be obtained the shots must be fired at comparatively close intervals. This necessitates a large number of shots per acre, and even allowing that the most economical means of charging and firing the holes is adopted, the cost must be very considerable.

Assuming the cost of one plug of gelignite with necessary fuse and detonator to be 2½d., add to this the cost of boring and charging the hole, and I think that 4d. is the very lowest estimate at which it can be placed. Now we have to consider the number of shots per acre required to give a good uniform breaking of the soil and subsoil; and if anything equivalent to subsoiling is to be obtained, I consider one charge equal to 4 sq. yds. of surface. That is 1,210 shots to the acre, or a cost of £20.

So far as my own experience goes, I find that results vary exceedingly in soils of different physical natures. Clay soils, if too damp, will lift right out, throwing up the earth to form a cavity below, and accompanied by a certain amount of surface breakage. The same soil dry will shatter considerably below, with but little surface effect until the winter rains fall. The results will then be seen in a slight subsidence of the soil for a considerable area and defined by surface cracks. In the deeper soils, especially if somewhat gravelly with a fairly compact surface, the results of the explosions are very contradictory, and in such a soil I have seen a charge of gelignite up to four plugs make scarcely any surface impression. The explanation of this will probably be found in the fact that the more or less loose nature of the subsoil absorbed the shock of the explosion. Exactly similar results followed where a thin crust of limestone overlaid a marly subsoil, and beyond the burnt fuse appearing at the surface there was no evidence of explosion of even three plugs of gelignite.

Taking all these facts into consideration it may be assumed that for general subsoiling the use of explosives is not comparable to that of team work.

PLANTED LAND.

We have next to consider the improvement of soil conditions in an established vineyard or orchard.

It is a common experience to find vineyards which have been planted with no general preparation beyond ploughing 9in. to 12in. deep. I refer to vineyards particularly because a great number of these are in what may be classed as the better agricultural areas, where the subsoil is frequently tough and compact. Orchard lands purely we find are more confined to the deeper and alluvial soils.

It is true that a good hole is opened out where the vine is to be planted, but at the most this allows but a limited scope for root development. As a result, after a few years of active growth, the vines or trees settle down to a stunted condition, and in districts where rainfall is deficient and heat proportionately severe, the trees suffer from "die back," and are short lived. Vines, though exhibiting great hardiness and adaptability, also suffer in both their growth and fruit production. If, however, this soil had been well broken up, giving the plants a wider range for root development, the conditions would more nearly resemble those of the looser soils in the better districts. It is in this connection, I think, that explosives will be found to work at their best advantage.

In an established vineyard we are faced with the impossibility of working a big subsoiler team within the narrow rows, and although to a certain extent the same difficulty is not experienced in an orchard, yet the work done is limited to a central strip between the rows. The breaking of this strip of soil is certainly to be recommended, but what is more necessary is to get closer to the trees without doing unnecessary injury to the existing root system.

The plan I have adopted is to put from four to six charges around old trees, keeping about 6ft. out from the stem. The holes are put down 2ft. deep, and the charge consists of one to one and a half plugs of gelignite. This work should be done in the autumn after the fruit has been gathered, and represents a period when, in normal seasons, the ground is most likely to shatter readily. When in this condition there is a distinct general lift of the soil without much surface breakage, and when the winter rains fall the affected area is marked by a general subsidence of the surface, indicated by cracks which may range from a diameter of 15ft. to 20ft. There is bound to be more or less of a cavity produced by the explosion, and ultimately this becomes filled with surface soil which may reasonably be expected to distribute itself through the larger fissures in the subsoil. This fact alone must be of advantage to the trees, placing at the disposal of the roots a quantity of rich surface soil. Another possibility arises from the results of this practice, and that is the introduction into the explosion cavity of some manure such as bonedust or superphosphate, which materially overcomes the difficulty of placing these manures within easy reach of the roots.

From personal observation I am of the opinion that old trees which have become stunted under conditions such as have been described, but which are otherwise healthy, will derive considerable benefit from this treatment, even without the addition of manure.

In dealing with a vineyard it is not to be expected that results equal to subsoiling could be obtained; but even so, much good will, I think, follow from even a limited use of explosives. Take as an example a vineyard planted 10ft. by 7ft. Place charges up the centre of the rows and at the intersections of the cross lines from the corners of the 10ft. by 7ft. parallelograms. Roughly, this means that one shot affects 8 sq. yds. of soil, or a total cost of £10 per acre on the basis of the figures already given. In actual practice over an area this cost might be reduced.

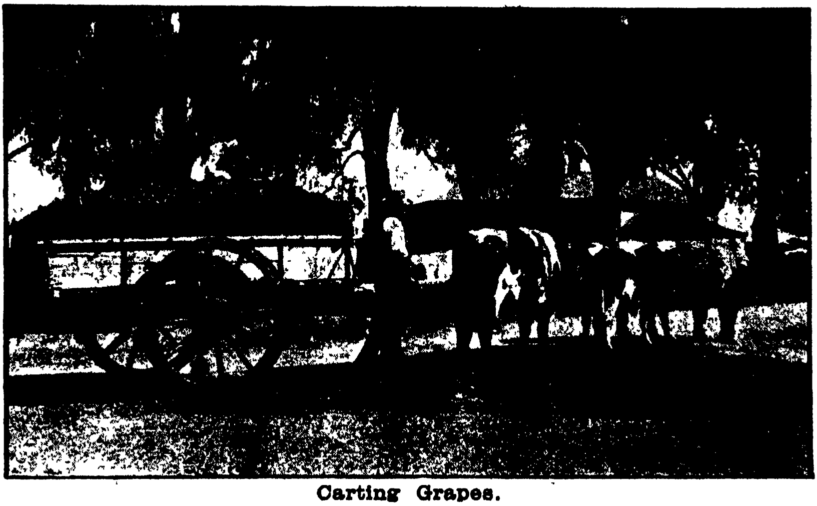
In the absence of definite data it is only reasonable to assume that benefit to the vines must result, and the value of increased returns would soon recover the extra amount of capital involved.

Finally, there is the question of planting young trees where total subsoiling is, for various reasons, impossible ; such as the filling of blank spaces in an orchard. The difficulty of filling a blank where the soil has become impoverished by a previous tree is well known, and to overcome this a loose soil for free root development is essential, and in this respect explosives answer very well. A plan to be recommended in such a circumstance is to put down three holes on a 4ft. or 5ft. triangle, the centre of which is the spot to be occupied by the tree. Use for each hole one to one and a half plugs of gelignite, and fire simultaneously. Afterwards the necessary hole can easily be taken out by a spade or fork.

The advantage of three holes over one central one is, in the first place, that a greater area of soil is broken up and there is no central cavity to subside afterwards and take the tree down with it. The young tree is, in a sense, planted upon a pyramid of loose earth caused by the explosions and all around it are fissures and cavities which fill with fine soil and into which the roots easily lead.

GELIGNITE.

In the selection of explosives one has a choice of several, but probab'y that of greatest convenience and utility is gelignite. It is maintained by some that this explosive is too sharp or quick in its combustion, and for some soils a slower explosion gives best results. It must never be forgotten that there is the element of danger associated with these explosives of high power, but given reasonable precautions, there is no more danger than in handling a tin of benzine. Nobel's gelignite is sold in 5lb. boxes, 50 plugs to the box. Proper implements are obtainable for cutting fuse and crimping on the detonators, and the man who does this latter with his teeth is taking a quite unnecessary risk. Want of care in fixing the detonator is often responsible for a miss-fire, such as failing to shake out the sawdust packing. In this case it is best to place a second charge as close as possible to the first one after several hours have elapsed. The second shot will then explode the first. For boring the holes an ordinary 2in. auger answers the purpose well, especially if it is bull nosed ; but I hope before long to see a simple machine obtainable which will expedite the operation and materially decrease the cost.



Carting Grapes.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board was held at the Roseworthy Agricultural College on November 12th, 1913, there being present—Mr. G. R. Laffer (Chairman), Messrs. G. Jeffrey, C. J. Tuckwell, J. Miller, C. E. Birks, A. M. Dawkins, F. Coleman, Col. J. Rowell, C.B., Professors W. Lowrie and A. J. Perkins, and G. G. Nicholls (Secretary).

General Business.—Correspondence was dealt with in reference to dispute at Bandon Branch. The Board decided that it could not recommend the establishment of an experimental farm between Lucindale and Keith, and that the matter of compulsory registration of stallions, which had been fully dealt with by the Bureau, could not at this juncture be re-opened.

Branches.—The Branch at Bowmans was closed owing to lack of interest, and a new Branch at Beaufort was approved, with the following gentlemen as members :—Messrs. W. W. Mugford, H. C. Underwood, A. E. Sampson, C. Wilson, T. Warner, W. B. Sampson, W. C. G. Underwood, H. B. Warner, W. C. Veitch, J. Dohse, A. Tard, J. Sampson, P. H. H. Underwood.

New Members.—The following gentlemen were approved as members of existing Branches :—Yadnarie—E. Stubing ; Uraidla and Summertown—S. E. Fleming ; Belalie North—C. Trimlett, C. M. Coleman ; Coorabie—A. Oats, J. Hanson ; Naracoorte—W. Staude ; Carrieton—J. Read, S. Manning ; Parilla Well—A. Inkster ; Clare—R. H. Atkinson, F. Schultz ; Salisbury—R. G. Robertson, R. W. Cilento, J. J. Bonnar ; Maitland—W. Maloney ; Leighton—T. Bailey, R. Earle, S. Williams ; Mallala—R. H. Oliver, J. A. Arnold ; Friedrichswalde—H. Klante, R. Zerna, F. E. Pfitzner, A. Luhrmann, E. O. Pfitzner, W. Beisel ; Butler—L. G. Parkes, P. R. Parkes ; Yallunda—H. Hissey, M. Hissey ; Strathalbyn—J. A. Pyne, R. H. Haines, E. S. Walsh ; Arthurton—H. J. Coote ; Mitchell—A. Baker ; Port Broughton—R. H. Evans, G. Tothill, A. Campbell ; Monarto South—V. Braendler ; Kybybolite—S. Shepherd, E. Leishman ; Elbow Hill—T. B. E. Wake, G. Brooks ; Bandon—H. P. Beckmann, T. Copp ; Mount Gambier—H. MacCormack ; Watervale—S. Haines ; Wirrabara—J. Bowmar, D. Stuckey, J. Jericho, D. Anderson ; Moonta—O. P. L. Payne, V. G. Critchett, E. H. Martin, J. W. Ortloff, A. H. Waters ; Stockport—A. Bald, G. Cant, A. Bott, T. Fidock, J. Howard, G. Howard, F. Koch, W. G. Wait, J. Rohde, W. H. Stevens, R. Whitelaw, W. Williams, R. Williams, W. B. Woodhead ; Renmark—T. C. Angove ; Mount Remarkable—R. H. Botten ; Keith—M. Crooks, W. Till ; Coonalpyn—T. Cratty, M. Cratty ; Hartley—G. Camac ; Hookina—A. Huddlestone, B. Kelly ; North Bundaleer—F. G. Sanders, P. R. Niell, A. Coon ; Clare—H. Mayor, P. A. Cichon ; Blackwood—J. L. Light, P. W. Light, C. D. Goutch, F. Chapman ; Morphett

Vale—H. Gum; Beetaloo Valley—G. Carter, C. Bond, H. Fradd; Crystal Brook—V. H. Johns, N. E. Heaslip, V. Tyler, F. E. Burgess; Maitland—E. Moloney; Wirrega—C. Meier, F. Meier, E. Meier.

Inspection of the Farm.—Members made a thorough inspection of the College Farm, and were very much impressed with the state of the crops despite the unfavorable season, which, up to a few weeks before, had threatened to bring about a complete failure. Items of special interest were the luxuriant crops of Egyptian clover (berseem), without which, Professor Perkins said, it would have been impossible to maintain the dairy herd; also a College bred wheat (Queen Fan), which was quite free from rust, while many other well-known varieties were badly affected by the disease; and 70 acres of sorghum, which it was anticipated would yield about 1,000 tons of greenstuff during the summer months. Other details of the tour of inspection have been fully published in the daily press, and are, therefore, not repeated here. Before leaving the College the party was entertained by Professor and Mrs. Perkins at afternoon tea, and the Principal and staff were heartily congratulated upon the excellent work being carried on, the value of which to the State it would be impossible to estimate.

ADULTERATION OF SEEDS.

JOINT ACTION ADVOCATED.

Probably there are few things of more importance to agriculturists generally than that they should be able to purchase seeds true to name and free from adulteration. In the old world this question is receiving increasing attention, and the following letter from the International Agricultural Institute, Rome, which has been forwarded by the Prime Minister to the State Government, should prove interesting. Although very little of the seeds referred to are purchased by South Australian farmers, the letter shows the necessity for exercising care in procuring seeds and also, incidentally, to some degree the extent of adulteration practised. Bearing on this matter, it would be well for any person having a knowledge where fraudulent practices in regard to seed adulteration have locally been carried out or attempted to communicate with the Department of Agriculture.

" International Agricultural Institute,
" Rome, September 6th, 1913.

" The Honorable the Minister.

" We have the honor to inform you that since the Fourth General Assembly, M. de Jaczewski has presented, in the name of M. Isatchwiko, Director of the Experimental Station at the 'Jardin Imperial' of St. Petersburg, a report on the question of the adulteration of seeds.

" The activity of the stations for seed experimenting in the different countries is hampered by the absence of cohesion in their efforts and to their not being immediately cognisant of each fresh case of adulteration of seeds or blending of harmful products, to such an extent that the stations are unable to take the necessary measures for the defence of agricultural interests. This results from the fact that the reports of experimental stations are generally somewhat belated, are not widely circulated, and even in certain instances appear annually only.

" Take, for example, the Russian clover, especially the Perm variety, which enjoys, as is known, an excellent reputation as seed material. As a consequence of the demands from abroad for this clover, caused in part by the poor harvest of 1912, seed merchants on the western frontier of Russia bought up wastes of Perm clover, mixed them with varieties of Southern Europe and America, and passed them off as Russian clover. Similarly on the Russo-German frontier, some years ago, large quantities of *Silene dichotoma* (which comes from waste Russian clover) were bought, mixed with the seed of the clover of different species, and were sold under the fictitious name of Russian clover. Instances of this kind are known in the experience of almost all experimental stations.

" To counteract as much as possible practices so inimical to agriculture, M. Isatchwiko, Director of the Experimental Station at the 'Jardin Imperial' of St. Petersburg, proposes that experimental stations, upon discovering cases of falsification or mixing of harmful products in seeds, should immediately advise their central station, upon whom it would devolve to immediately publish the facts in a special bulletin. It would be equally incumbent upon that station to immediately inform the International Institute of Agriculture, at Rome, who, on their part, would, in the interests of agriculture, give it publicity in their monthly bulletin."

THE WHEAT CROP.

Official Forecast: Probable Average, 9·39 Bushels.

Under direction of the Government Statist (Mr. L. H. Sholl, C.M.G.) the work of compiling the official estimate of the wheat and hay harvest was completed by the Chief Clerk (Mr. W. L. Johnston) and other officials of the department on November 30th. The actual figures for the past season and the estimated ones for the present are given in detail in the following pages. In the table below the official totals for the State are shown, together with the estimates of *The Advertiser* and *The Register*.

1913–14.	Government Statist, Dec. 1st, 1913.	*The Advertiser*, Nov. 13th, 1913.	*The Register*, Nov. 15th, 1913.
	Acres.	Acres.	Acres.
Area under crop	2,529,022	2,575,017	2,566,000
Area to be reaped for wheat	2,076,064	2,090,017	2,131,622
Area to be cut for hay	452,958	485,000	433,818
	Bushels.	Bushels.	Bushels.
Aggregate wheat yield	19,491,585	17,268,730	18,992,742
Average per acre	9·39	8·25	8·91
	Tons.	Tons.	Tons.
Aggregate hay yield	515,331	—	405,619
Average per acre	1 ton 14cwts.	—	18·7cwts.

The report shows that the total acreage under crop is 43,591 acres less than in the preceding season, and that the estimated production of grain is less by 2,004,631 bushels, and of hay by 41,113 tons. The only division of the State in which an increase on last season's wheat yield is shown is the South-Eastern, where it is anticipated 112,596 bushels more will be reaped. "In the Far Northern and Far Western Divisions," states the report, "dry conditions prevailed throughout the season, and the crops in those areas are either absolute failures or else yielding but a bushel or two per acre." At one period of the season the outlook could hardly have been more unpromising, but the favorable weather conditions experienced in most of the agricultural areas in the two critical months, October and November, saved the situation. That with the season experienced so favorable a general result can be indicated is testimony alike to the recuperative power of the soil, the cultural methods of most of our farmers and the vitality of the wheat plant.

The following shows the estimated averages per acre for each division in comparison with the actual for the previous season :—

Division.	Average per Acre.	
	Grain. Bushels.	Hay. Tons
Central	10·41 (10·97)	1·26 (1·24)
Lower North	13·14 (13·99)	1·16 (1·20)
Upper North	3·92 (8·42)	0·67 (0·91)
South-Eastern	9·39 (9·51)	0·94 (0·83)
Western	6·02 (6·46)	0·78 (0·68)
The State	9·39 (10·34)	1·14 (1·13)

Statistical Department, Adelaide, November 29th, 1913.

L. H. Sholl, Government Statist.

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

During the ensuing months the weather in most parts of the State will be warm. In many country localities the farms, and as a rule the poultry runs, are much exposed. On many of the older farms there are thatched barns and sheds wherein the poultry congregate on hot days and find moderately cool quarters. Unfortunately, in a number of cases these old barns swarm with vermin (ticks and red mites). In many suburban and town yards there is very little provision of shelter. Many people must be either callous or foolish. It is most cruel to expose fowls unduly to the hot sun. Those who think it natural for bird or beast to exist in the hot glare should be taught better. I am glad to notice that the Society for the Prevention of Cruelty to Animals is championing the cause of ill-used poultry. I trust that the Society will also initiate a crusade against those who do not provide proper accommodation for their birds. Many people constantly prate about the value of tree shelters. These are not always available, nor are most trees suitable for poultry runs. The best and most enduring shades are made of galvanized iron, which is quite cool if two coats of King's compo. are applied. The iron should rest on a frame, and should be close to the ground at the back (north) and about 18in. to 24in. high in front (south). A good shelter can be made of sacking or hess an-stretched on a similar frame and covered with two coats of King's compo. These will last two or three years and are cool. All iron poultry houses should have the roof and other parts exposed to the sun painted with two coats of King's compo. This is what is always used at the Poultry Station.

Vermin.

Last summer hundreds of cases of sickness were investigated, and in nearly every case the trouble was due either to poultry ticks or to round worms. In many cases owners protested that there were no signs of poultry ticks; but in every case where the symptoms pointed to the effects of ticks these parasites were discovered. In many cases there were only a few adult specimens met with; there were always to be found numerous larvæ (the six-legged young ones). These almost invisible greyish young ticks are quite as deadly as the large ones—they all carry and distribute the spirochaete which causes tick fever. I often notice ignorant remarks on this subject, but the fact remains—the ticks cause the trouble, and must be eradicated. Makeshifts, such as patent and swinging perches, are of no permanent value—the pest must be eradicated in all cases. Those in doubt can obtain, gratis, a bulletin on this subject on application to the Poultry Expert, Adelaide.

All mites and lice must also be destroyed. Kerosene will kill all ticks, mites, and lice.

Worms are generally to be found at about this time of the year, and later on many of the most promising pullets die. It is a very simple matter to diagnose a case of worms. The young stock frequently appear to have roup; there is a nasal discharge and a rattling in the throat. The birds have an abnormal appetite and soon get thin—diarrhœa, generally greenish and offensive, sets in, and then death. If the bowels be slit longitudinally and the contents examined, the thread-like round worm will be found. In some cases they obstruct the passage; but even two or three will cause death. There are several sorts of worms—*heterakis*. A small one is *papillosa* and the larger ones, up to 3in. long, *inflexa*; some are less than a third of an inch. long. The best cure is 1 part santonine and 7 parts ground areca nut. Dose for a single bird, 7 grains; for the flock, one heaped teasponful to each 20 adults. The birds should be fasted for at least 12 hours, and the powder should be mixed thoroughly in dry bran and pollard, which is afterwards moistened. If these matters are attended to less will be heard of sickness and losses.

CANNIBALISM.

Several complaints have reached me of cases of cannibalism. Hens when laying occasionally experience trouble—very often they are over fat. In straining to pass the egg they stand up and expose the protruding parts. Other hens will, as is well known, attack any hen which is bleeding, and, although there is perhaps no bleeding, the hens think so, and will attack and fatally injure the laying hen, which is, as a rule, helpless.. The best safeguard is to have secluded and darkened nests, so that when a hen goes in to lay she will not be molested. The Chapman patent trap nest is a good preventive of this trouble, as only one hen at a time can enter to lay. An iron carbide drum placed with the opening against the side of the house makes a good nesting-place. The trouble is generally confined to Leghorns.

YOUNG STOCK.

Separate the sexes and cull out all poor specimens; market them as soon as you can get them fit. You will then have more room for the selected stock, and can give them more attention. Do not unduly force the young stock. Keep the young pullets from laying too soon. Let them grow a good frame—have them big and strong. Frequently change them from yard to yard; give them good oats and plenty of succulent green food. Precocious cockerels, which look developed when the size of pigeons, can be transferred to the "pot" yard; such birds are generally weeds and not worth rearing. Look after some that are less precocious and growing; these generally make up into far better birds. You can always find plenty of culls. Keep the best only; the others are not worth while.

Ducklings should be well sheltered from the sun. They must have plenty of clean fresh water day and night; the containing vessel should be deep enough to enable the ducklings to totally immerse their heads. Give them as much cut green food as they can eat. Provide grit and charcoal. Ducklings for market should be pushed along and fattened for sale at about eight or nine weeks—the earlier the better.

TABLE POULTRY.

There 's room for much activity in breeding table poultry. Nearly everyone I speak to on the subject—more often they come to see me—complains of the difficulty in obtaining supplies, and they also complain of the wretched fleshless birds in the markets and at the poulterers. There is plenty of money in table poultry breeding. If the wholesale buyers will not pay, then advertise your birds and sell privately. There are hundreds of buyers who will gladly pay a fair price for a good table chicken or duckling.

THE LAYING COMPETITIONS.

Intending competitors are informed that regulations and entry forms are obtainable at my office. Early application is necessary, as there are only a limited number of pens available this year. Entries are coming in freely, and those breeders who enter will be allotted the pens: there will be no ballot.

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

HEALTH.

The birds are in good health. During the month there were six deaths, three from excessive heat and three from various other causes.

BROODINESS.

There were 160 cases in all, contributed by the following sections:—No. 1, 68; No. 2, 75; No. 3, 17 (including 4 Langshans and 7 Black Orpingtons). The high total of 68 in section 1, all Leghorns with the exception of one pen, shows that this serious fault has not been bred out of our Leghorns. Unless the greatest care is taken to exclude from the breeding pens all hens which have even once shown signs of broodiness, the time will come when our Leghorn flocks will be seriously deteriorated. It is a matter of breeding.

EGG PRODUCTION.

The eighth month has passed, and one may now offer a few figures comparing the result of the present test with those of former years. For the purpose the two previous tests have been included.

OPEN SECTION, NO. 1.

	Pens.	Eggs Laid.	Average per Pen.	Ten Leading Pen Averages.
1911-12	101	69,768	690·7	842·3
1912-13	83	63,183	761·2	930·8
1913-14	102	80,203	786·3	963·2

SECTION 2—HEAVY BREEDS.

	Pens.	Eggs Laid.	Average per Pen.	Ten Leading Pen Averages.
1911-12	25	15,821	632·8	720·2
1912-13	31	18,966	611·8	710·9
1913-14	21	13,799	657·0	755·0

TOP SCORES.

	Section 1.	Section 2.
1911-12	969 (Redfern)	836 (Craig)
1912-13	1,042 (Uren)	757 (Martin)
1913-14	1,039 (McKenzie)	920 (Kenway)

HIGHEST SCORES.

1911-12 .. 1 pen over 900 (White Leghorns) and 8 pens over 900 (White Leghorns)
1912-13 .. 1 " 1,000 " and 11 " 900 (White Leghorns)
1913-14 .. 2 " 1,000 " and 1 pen Black Orpingtons

The above figures may be considered satisfactory, especially in view of the fact that the "man in the street" freely prophesied that as the number of pens increased the scores would decrease. It will be noted that in the year 1911-12, when the official world's record was made (1,589), the pen which won had scored only 969, as against 1,039 for the leading pen in the present test. Then again, the good general averages show solid progress. In the record year there was but one pen over 900; this year we have 13 pens, including two over 1,000.

It must be remembered that in the history of the South Australian Laying Competitions the first good score came in the year when good housing was adopted. The superior houses at Parafield have no doubt contributed to the present state of affairs. During the next four months we may, of course, see many changes.

VISITORS.

Early in the month a large party, organised by Mr. T. H. Pitman, of *The Mail*, visited the poultry station. Other visitors attended, bringing the total up to 250. The month's total was 298, and the total to date 754. Judging by press comments and correspondence, the visitors have derived much benefit, and the station will serve as a centre of information.

WEATHER.

Temperatures generally mild, but with cold winds on several days. The total precipitation was 1·26, with some heavy showers.

D. F. LAURIE, Poultry Expert and Lecturer.

CONFERENCE OF HILLS BRANCHES.

(Continued from page 524.)

AFTERNOON SESSION.

CULTIVATION OF THE POTATO.

Messrs. Pope Bros. read a paper as follows :—" Two factors essential to successful potato culture are good cultivation and good seed. To get the best results these two must go hand-in-hand, or a good deal of the profit will be lost. The potato crop is an expensive one to plant, and if it turns out a failure a big loss is likely to be incurred ; therefore the very best results should be aimed at, and every minor detail should be looked after. We know of no crop that causes more backache and grumbling to harvest than a poor potato crop.

CULTIVATION.

" The land should be ploughed as early in the spring as possible, when the ground is in fit condition. Do not work the soil when it is too wet ; it is better to be a little late and have the soil in good order than plant early and have the ground wet, so that it runs together and bakes when the weather becomes hot, as it soon loses the moisture when in this condition. If the land is heavy, work it to a depth of 4in. or 5in. the first ploughing, and then go deeper the second time. If using farmyard manure this should be carted on before the first ploughing in order that it may be well worked into the soil. Fertilisers should be drilled in after the first ploughing some time before planting. Cultivate well after each ploughing and after each rain, as it helps to retain the moisture and the land works down much finer after being exposed to the sun when it gets a rain on it. One cannot give potato land too much cultivation at the right time. Deep ploughing is absolutely necessary, especially for summer planting. Don't be afraid of a little clay coming to the surface ; it will do no harm. It is better to bring it up and loosen the ground than leave it there and not loosen it. Plenty of cultivation before planting saves working afterwards and keeps the ground clean of weeds. In a district like this, with a heavy winter rainfall, weeds are troublesome. One of these is sorrel, and once it gets hold of the soil very little else will grow. We know of no better way of getting rid of this pest than working the land for potatoes in the summer. Cultivation for potatoes will also help to clean the land of wild oats. Thus, with potato cultivation, we are cleaning the land and enriching the soil. About two-thirds of the land in this district is suitable for this crop—the heavier soil for October-November planting and the lighter soil for December. Potatoes should not be grown on the same soil more than twice in succession ; rotation of crops is necessary.

They prefer new land to land that has been under cultivation ; but this cannot always be had, therefore we recommend a crop of peas grown directly prior to a potato crop, either ploughed in or harvested. Our experience is that a crop of peas ploughed under, with 4cwt. of super. and 2cwt. of bonedust, will almost double the crop. It is the next best thing to farmyard manure and much cheaper, and will build up the land for future crops.

The Seed.

" Large cut seed gives by far the best results, but it is much more expensive to plant than round small seed. It does not always pay to plant large seed on account of the cost of the tuber and the extra cost of cutting. We believe equally profitable results can be obtained because of the less cost from round seed, but this must be grown from large seed. There is no seed that will degenerate so quickly as the potato. For one planting a fairly large area the cost is a big item, and we recommend round seed for early planting, as it is not so likely to rot ; and also for late planting if there is a lack of moisture, for the round seed will germinate where the cut will not. Select the seed from the best plants, lay them out thinly, allowing them plenty of light. Under pine trees is the best place for them. Turn them over every two or three weeks, using a shovel. Rain does no harm. After they have become green frost will not hurt them. Do not let the hot sun shine on them, as it injures the shoots. If short of room, and there is no convenient place to store them, put them into old super. bags and let them remain anywhere in the weather through the winter so long as the wet does not lay under them. They will keep better this way than stored in a barn.

Potatoes as a Main Crop.

" If a storm damages the peas and hay there is some consolation in that it is not also spoiling the potatoes. We have never yet experienced poor crops of hay, peas, and potatoes during the same year. If one has been poor the other has been good ; hence the wisdom of including potatoes as one of the main crops. As soon as we have finished with one the other is ready, and as soon as we have sold one we can start selling the other, and there is always money coming in. We strongly advocate late planting for these reasons. If we plant early, say, at the end of August or beginning of September, we will almost be sure to encounter frost or a heavy fall of rain which will set the ground down hard, and it then quickly loses the moisture and rots the seed. Just when we want the moisture to form the tubers, hot, dry weather sets in, the ground is baked down hard, and the moisture is gone. If we try to cultivate them then the ground breaks up cloddy, and trouble is experienced with the grub. Early potatoes will not keep as well as late ones. Ir growing late crops soil of a sandy nature which can be kept worked is needed. This should conserve enough moisture to keep the crop going for eight or 10 weeks, planting from the middle of December to Christmas. To do this a late variety is needed. By the time the tubers begin to form in March, or early in April, the days are getting shorter, and nights dewy, and rain is more likely to fall when the potatoes need it. They will keep better, be freer from worms, and be of a better quality. Some growers are not successful because they do not plant the right variety at the right time. It is a bad policy to plant a late variety early; they will very seldom do any good. There are some varieties that do well early and late, such as Carmen No. 1 and Pinkeye; but it is absolutely no use planting Snowflakes early. Plenty of tops will be secured, but no tubers. It always pays to get a change of seed every two or three years, as the following experience will show:—From old seed grown in the same class of soil for some years from 11 rows we dug 15cwts., and from five and a half rows of imported seed grown alongside we dug 30cwts., the old seed going about 2 tons and the imported seed about 8 tons per acre. This soil was well cultivated, but the difference of the results clearly shows that it does not pay to cultivate well and have run-out seed. It is usually the custom to sell all the best and plant the worst of the tubers and leave none for the pigs.

WHEN AND WHERE TO PLANT.

This is a wide subject, and all depends on the locality, the kind of seed planted, and the nature of the soil. In what some call good potato land, *i.e.*, black flats, they should be planted about October and November with Carmen No. 1, Brownhill Beauty, Pinkeye, or Excelsior, or varieties of that kind. For late planting there is no variety to beat the Snowflake. This does better in sandy loam, and should be planted about Christmas time. We have never had a failure yet with this variety, planted at the time recommended on well-worked sandy soil. Many growers make a mistake in planting the wrong variety at the wrong time. One thing is to grow a good crop and another is to find a good market. The farmer is often to blame in the way he markets his produce. With some people anything will do, and they send a bad lot to market, and this often results in a bad name for the whole district: the guiltless have to suffer with the guilty. Inspectors should have more power to reject the inferior article and make room for the good."

Mr. C. Ricks congratulated the writers of the paper. He was not quite clear whether the crops referred to had been irrigated.

Mr. Pope said they had found that cultivation to conserve moisture in the soil was better than irrigation.

Mr. T. Jacobs said the advisability of planting potatoes on the same land twice in succession depended on the nature of the soil. He had a piece of ground on which 73 successive crops of tubers had been grown, and the present crop was looking well. He usually secured from 4 tons to 12 tons per acre from the land.

Mr. Pope thought the yield would be nearer 20 tons if other crops were put in occasionally.

Mr. Pearson (Meadows) said irrigation was advisable under certain conditions. It did not matter how often the ground was cultivated, they could not grow crops without irrigation in his locality. The water was put on by gravitation. He agreed with Messrs. Pope as to the varieties they were growing. Snowflakes did well at Meadows; White Elephants were of little use. Potatoes should be worth £2 per ton on the farm for feeding to stock.

Mr. A. Beviss (Strathalbyn) asked whether it was detrimental to put the manure direct on to the potatoes.

Mr. Pope advised working the manure well into the land as the better practice.

Mr. E. J. Oinn (Longwood) asked whether sulphate of potash or nitrate of potash had been tried on this crop.

Mr. Pope said that on new land, according to experiments, the potash had been of great benefit when used at the rate of 1cwt. per acre with super. and bonedust. Last year, whilst the tops looked better there was little difference in the returns. They had never tried cutting back the tops of the potatoes when they grew very heavy.

Mr. J. Morris (Mount Barker) had cut back part of a crop, but the portion so treated did not yield as heavily as the other.

Mr. H. Jones (Mount Barker) asked whether they had tried ploughing in white mustard as a green manure.

Mr. Pope had done so, and the crop following had been an excellent one.

Mr. W. H. Hughes (Woodside) thought the paper a very practical one. The practice he adopted was, after ploughing in peas, to put in farmyard manure when they were planting the potatoes. He was of the opinion that there was very little difference between ploughing the manure in when the potatoes were being planted or ploughing it in earlier. The broad bean was an excellent crop for ploughing in. This collected nitrogen from the air, and it did not tangle as much as the peas. Whether irrigation paid or not depended entirely on the source of the water. He was sure it was remunerative in some instances in his district, and where it was practised it would be found that there were very few small tubers in the crop. The Snowflake was a very heavy cropper, but it sold at low prices. It was a question whether it paid to grow this variety—securing a large crop, but at the same time getting lower prices for it. When there was a glut of potatoes, he thought it did not pay to grow Snowflakes. Not many years ago these were quite unsaleable, and if there had been a good crop this year conditions would have been similar. It was necessary to find a market before they went in for growing potatoes extensively.

Mr. Pope agreed that irrigation paid in some cases, but if the crop were watered and a heavy rain fell immediately afterwards there was a danger of the tubers rotting. Snowflakes grew well in sandy soil. Growers in the hills were nearly £1 per ton nearer the market than those at Mount Gambier. He planted the tubers at a depth of about 4in. to 5in. The crop was worked very little in the summer; perhaps he went over it with the cultivator once or twice. He had never tried adding salt to the land to be planted with this crop, but he had ploughed in ½ ton to 1 ton to the acre for mangolds. He strongly recommended harrowing after the plants started growing.

Mr. Stephenson (Mount Barker) asked which was the more likely to suffer from frosts—a crop that was irrigated or one that had not been so treated.

Mr. Pope said the irrigated crop was less liable to damage.

Mr. Giles (Mount Pleasant) asked whether Mr. Pope had tried any frost-proof potatoes.

Mr. Pope had tried reputed frost-proof varieties, but they had not successfully resisted the frosts.

Mr. Pearson mentioned a potato grown in New Zealand which was apparently immune to frosts.

Mr. A. F. Furniss (Woodside) asked whether Mr Pope pickled the seed before planting

Mr. Pope did not do this.

Mr. Johnstone (Uraidla and Summertown) asked whether it was advisable to sow seed grown in the district; also whether the writers of the paper had experienced any trouble with Irish blight. At Uraidla they always made a practice of irrigating. The Snowflakes generally did not grow until there was a fall of rain, with the result that there was usually trouble with Irish blight or rotting. There was less trouble with Carmens and Prolifics in this way.

Mr. Pope said best results would be secured from imported seed, but the "come up" was not so good. They had not been troubled with Irish blight in this district. The quicker the potato grew under irrigation the better. For putting in areas of 20 acres or 30 acres, as they did, the Snowflakes could not be beaten.

A delegate had found it very profitable to irrigate. He quite agreed with the writers of the paper on the question of manuring. He drilled in the manure, working the land thoroughly and getting it as fine as possible. After planting he cross-drilled the manure and irrigated. Had Mr. Pope had any experience with scab?

Mr. Pope explained that where they put in large areas it was not possible to irrigate. They had not been troubled much with scab. Pinkeyes had been affected, but other varieties had not been.

Mr. Quinn mentioned, in connection with the question as to how long potatoes might be grown on the same land without a change of seed, that he had been recently looking through the latest journals of the Horticultural Societies of England, and at Wisley they had a station where they tested matters of this nature. One man had grown his own seed of Ash Leaf kidney for over 50 years on the same land, and the yields were quite equal to the very best of 160 varieties grown from changed seed.

Mr. Ellis asked whether the writers of the paper had met with success in the use of the potato planter and potato digger.

Mr. Pope said the former had been a great success. The digger was very useful in a light crop.

Mr. H. A. Monks (Mount Barker) asked whether Messrs. Pope had had any experience as to the profitableness of feeding pigs on potatoes.

Mr. Pope did not think it would pay to feed these on potatoes at £2 per ton.

Mr. Pearson had fed a pig on potatoes and it did remarkably well; it was purchased for 10s. and six months later sold for £3.

Mr. Monks mentioned that the price of pigs at present was very high, and it had occurred to him that it would pay them to grow potatoes for feeding to these animals as well as to cows.

A delegate had been feeding pigs on boiled potatoes and pollard, and this certainly paid him.

Professor Lowrie said if it would pay to feed pigs selling at 5d. per pound on potatoes at £2 per ton, there were many crops that would give more profitable feed. If the growers at Mount Gambier could always secure £2 per ton on trucks Mount Gambier they would do very well. He could not contemplate feeding potatoes at that price.

Mr. C. Ricks made a practice of feeding small potatoes to cows. He threw them into the paddock and the animals ate them uncooked.

FALLOW OR ROTATION.

Professor Lowrie said that in the Hills districts farming was a very different proposition to what it was in the wheat-growing areas of the North. The best of the wheat country enjoyed an average annual rainfall of from 15in. to 20in., but the precipitation in the southern hills was usually far in excess of that. Yet there was a hankering on the part of some farmers to imitate the methods that were so successful further north. Some were keen on bare fallow—a thing that should be discounted where the rainfall was more than ample. In low rainfall areas it was justified to conserve moisture, but here the reasons for it did not operate to the same extent, although thorough bare fallowing might pay as a check on sorrel, drake, &c. If there was room anywhere for a system of rotational cropping, it was in the hills. They had a range of qualities of soil from very best down to the very worst. He was satisfied that even the poor, cold, raw soils could be made to yield profitable crops, but doubted that the inferior ironstone country could be made fertile economically. Bare fallowing was all right on land worth from £2 to £7 per acre that required the rainfall of two seasons to grow a full crop; but why in the world did they do it on well-watered lands worth £14 per acre? They had the facilities of growing a full crop without bare fallow. Three months previously, at a meeting at Mount Barker, he had urged them to use more lime. He had been under the impression that lime had not been used in the hills since the dawn of farming. He had since found that one or two old English farmers still carted out lime to the fields and harrowed it in.

LIME.

There was no element so likely to become deficient as lime. It was 60 times more liable to leach out under a heavy rainfall than potash or phosphates. The time was approaching when they would have to use it. The previous week he had secured three samples of soil from Mr. Pope, taken from what was classified as "good," "medium," and "poor" land. Analysis showed the good land contained ·65 per cent. lime; medium, ·12 per cent.; and poor, ·18 per cent. When the amount of lime was reduced to ·12 or even ·18 they might cultivate with the greatest skill, and apply other manures, but they would get more or less disappointment. It was commonly recognised that to remain productive the soil should have at least 1 per cent. lime; but when they got below that, direct application should be given. Professor Hall, one of the best authorities, put down the minimum as ·5 per cent. It was true that analysis was only an indication, but the figures should set them thinking. They could try the effect of applications of 2 tons of quicklime or 4 tons of carbonate of lime, and see how far it would go. The lime, its composition, and its influence on the soil, were described, and farmers were advised to try it on plots in their various fields before they concluded that it was not a profitable investment. The price for lime had been too dear to encourage its wholesale use; but freights had been reduced on the railways to the same level as fertilisers. They could buy 50-ton lots of seashells, containing approximately 84 per cent. carbonate of lime, at 10s. per ton, landed at Port Adelaide. A manure firm was also placing it on the market in a powdered form. If quicklime were preferred, farmers should co-operate to purchase a lime distributor. One ton to the acre was suggested as a suitable quantity, but they could put on two or three smaller lots of from 7cwts. to 9cwts. Twice as much seashells should be used as quicklime. He described the difference between the various kinds of lime.

DRAINAGE.

Drainage by means of tiles was not recommended for the farm on account of its cost; but in the orchard the method might prove economical. However, the farmer could make his land more productive by putting a single drain sometimes in such a situation as to tap the source of the water. Surface drains, as a rule, would prove equal to relieving the waterlogged condition of soil in the winter. Soil which was heavily waterlogged in winter was the first to give out for want of moisture as soon as hot weather came. By drainage they would secure aeration of the soil and encourage the roots to go downward instead of remaining near the surface to be parched with the first dry spell.

LEGUMES.

Legumes formed one of the most suitable crops in a rotation in the Mount Barker district. They were excellent for fattening stock, and in this way, as well as by nature of their nitrogen collecting from the air, they enriched the soil. He was not too keen in ploughing them under, preferring to feed them down where practicable. More use should be made of rape and mustard. The former was one of the best subsoiling plants they could use. In wet districts it was therefore of peculiar value. The presence of mustard would lessen the risk of loss of stock when feeding down. The seed could be sown after the rape had germinated if they were afraid of "seeding" up their land. Sheep did not care for mustard alone, but when put on a crop of mustard and rape they would go for the mustard first. Italian rye grass was an invaluable crop. They had to be careful, however, to make sure they were really getting what they ordered, as three-quarters of the seed on the market was not the real article.

Mr. H. B. Welch (Port Elliot) asked whether it was advisable to apply salt to the land in the Inman and Hindmarsh Valleys.

Professor Lowrie replied that while applications to the land might not be necessary it would be advisable to provide salt licks for the stock. A dressing of kainit might be applied. It was better to apply carbonate of lime than gypsum. The proportion of calcium oxide in gypsum was relatively small, only about one-third of that contained in a good sample of carbonate of lime. It did not reduce sourness; in fact, if they were continuously using it, it would encourage this condition. The gypsum might be of use in alkali country, such as was met with on the Murray. It was not necessary to apply lime to limestone land unless in exceptional cases. He would not recommend sowing lime through a drill, which was asking more than should be required of it.

Mr. Nicholls (Longwood) had for several years applied slacked lime to land in his district. He had found it altogether too costly. In connection with new land in the district it was found that bonedust acted very much more quickly than superphosphate. The conclusion he came to was that this was probably due to the fact that the land was very sour. Since lime had been used, much quicker and better results had been secured from the superphosphate.

NEXT CONFERENCE.

It was decided that the next Conference should be held at Longwood.

WEIGHTS OF SUPERPHOSPHATE.

Mr. T. B. Brooks (Clarendon) moved—"That it be made compulsory for all manufacturers of manures to stamp the weight of the contents on each bag." When they purchased manures, he said, there was a danger of their not receiving full weight. The Government Produce Department and the Abattoirs followed the practice, which it was proposed should be made compulsory. The loss to the farming community of South Australia in this connection ran into thousands of pounds yearly.

Mr. Phelps (Clarendon) seconded the motion. He thought the proposal quite a reasonable one. They had a right to see that they got what they asked and paid for. The loss occurred in connection with small lots, when 13 bags were purchased for 1 ton. If they complained to the merchants it was attributed to shrinkage or leakage. They had the quality guaranteed, and they should also have the quantity guaranteed likewise.

Mr. T. Jacobs (Cherry Gardens) failed to see that they would secure any advantage by having the weights printed on the bags. The fertiliser was bagged up when freshly made, and it gradually lightened. If he asked for a ton of manure he could demand the full ton weight, irrespective of whether the weight was branded on the bag or not.

The motion was carried unanimously.

EVENING SESSION.

SOME COMMON DISEASES OF THE PIG.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) delivered an address on this subject, in which he said—An old work on farriery, dating from the seventeenth century, prefaces remarks on diseases of swine with the following :—" The pig, like other animals, has many diseases ; but you may as well drench the devil as drench a pig." And after the lapse of 300 years there is still a great deal of sound common sense in the advice.

On the other hand, the pig is undoubtedly the best paying of all live stock, even if one does not go to the length of agreeing with a certain South Australian authority, who used to contend that one could get four litters a year from a sow. Still the practical certainty of two brings in a return on capital with a bountiful interest that cannot be expected of other farm animals. The economics of feeding swine show that there is a gain of 1lb. live weight for every 4½lbs. of dry feed given, as against the 1 to 10 of cattle, so that undoubtedly the pig is " the gintleman that pays the rent."

There is always a tendency in South Australia to ignore attention to the details of physiology and diseases of pigs and sheep owing to their small individual value ; but if one calculates them as intrinsic factors of a large proportion of the national wealth the importance of such knowledge must not be too lightly dismissed, especially when one considers that but a few years ago the losses from swine fever, plague, and tubercle in the United States of America amounted to £15,000,000.

Prevention is of far more importance than the treatment of disease or the wiping out of affected herds, and far cheaper, too; but the time to begin preventive treatment is six months ahead of an outbreak in the herd—in other words, attention to the physiology of the pig's digestive organs, cleanliness of its surroundings and hygiene of its body are things which no pigkeeper can ignore if he wants to make his pigs pay. Naturally one is inclined to smile at the idea of attending to such things when one thinks of the ordinary pig and the ordinary sty; but the fact remains that in its natural surroundings the pig is the cleanest of all our farm stock, and kept as we keep it it is the only one which makes its bed morning and evening, and uses as a privy the corner of its sty furthest from its resting-place. Its stomach is the most complicated of all our farm stock, and deals with a large variety of food in a most effectual way, disinfecting putrid meat or rotten fruit, to say nothing of the myriads of germs in the milk of the swill tub, in a fashion that no other animal could; and because it can do this we rather illogically conclude that it is not happy unless it is doing so, and put a tax on its digestive system that lowers its vitality and renders it liable to diseases such as swine fever, swine plague, tuberculosis, and so forth.

While pointing out these facts one does not necessarily imply that the grooming of pigs as attempted by a certain new boy at Roseworthy is desirable, or that they should shiver in a bare concrete sty because bedding might harbor a louse or two, or that they should contract rheumatism while becoming inured to a constant slushing out of their houses with the hose. But one does lay stress on the fact that breeds of strong vitality are most desirable: that feed of such character that the skin, the bowels, the kidneys are stimulated to carry out their duties regularly is what is wanted, accompanied by a certain amount of exercise: that clean houses and drinking water will do much to prevent the development of worms, lice, and other parasites which play a very important part in the spread of disease. While the excellent organisation of the Stock and Brands Department places at the disposal of the pigkeeper inspectors of experience and veterinary surgeons well versed in the diseases from which swine suffer, and as many of these are of a highly contagious nature, and as it is far easier to put out a small fire in its early stages than to attempt to smother it when it has a strong hold, it is not only the duty of a pigkeeper to report disease among his pigs to that department, but it is decidedly to his financial advantage to do so. Stock inspectors are not ogres whose one desire is a sacrifice of swine flesh. The stealthy burial of a defunct porker (*a la* Sir John Moore) at dead of night may be the natural action of a man desirous of hiding the evidence of his guilt; but to speak plainly it is a fool's proceeding, and one which will most likely only precede the loss of many more pigs, till in despair the help of the authorities will have to be called in, and naturally they will not be best pleased at finding an outbreak of disease which has been going on for weeks or months, and the measures they then have to adopt are far more drastic than they would have used earlier. As with all classes of livestock, the less medicine is resorted to with pigs the better for them and the more profitable for their owner. But one has to realise that human nature will insist on pouring medicine of some sort or other down an ailing pig. One of the most satisfactory ways of drenching a pig is to have a good strong slip over the snout and over a beam so that the pig is backed into a corner. Naturally he squeals. He cannot squeal and chew at the same time, so if an old boot with a bit cut off the toe is put into his mouth he stops squealing and chews. Then in comfortable sized mouthfuls poured down the boot he will swallow the medicine. If it is given too quickly he will choke or waste it. Small pigs can have the snout tied up and the medicine put into the corner of the lips, as with a dog; but the less they have the better.

It is a good plan to put any of the coal tar disinfectants, such as Jeye's or Pearson's fluids, in the swill, especially in hot weather, a pint or two to a barrel: this checks worms, maggots, and so forth, and helps digestion too.

There are also many simple correctives which are of great value to the pig, and can be given in the food, such as sulphur, coal, charcoal, wood ashes, Epsom and Glauber's salts, and limewater, to say nothing of patent pig powders, which usually depend for their efficiency on some of the above, combined with spices like fenugreek, aniseed, &c. Ground castor seeds are excellent medicine for a pig, from a ¼oz. to 2oz. in the feed, especially for worms, when a similar quantity of melon or pumpkin seeds help.

When dealing with disease in swine the first thing that comes into the mind is swine fever, in the same way that in the human being just now any innocent rash is suspected of being smallpox. On the other hand, swine fever is, fortunately, just about as rare as smallpox; but there is another and very similar disease, which is unfortunately more common in South Australia, called in Europe and America swine plague, but here contagious *pneumo-enteritis*.

It happens that the symptoms and general course of the two diseases have much in common, and from a farmer's point of view it will be as well to discuss them together, especially as the means to combat the two are practically the same.

In pigs the early symptoms of disease are not so marked as in other animals, and so it happens that very often the first intimation that anything is wrong is the death of a pig or two; but to the eye of the man who takes an interest in his pigs there are earlier signs, which should not be neglected. Fever, shivering, unwillingness to move, loss of appetite, with a distinct rise of temperature from the normal 103° to 106° or 107°. Have more than one thermometer, for breakage is very common in an unpractised hand. The pig is dull and stupid, hides in the bedding and is unwilling to leave it. At the outset the bowels may be normal, or even constipated, but later on an exhausting diarrhœa with a very typical smell sets in and persists. The eyes are congested and watery, and later a yellowish thick matter gums the lids together. The breathing is rapid and oppressed (in the later stages actually labored); while there is also a rather typical cough, not very frequent, but noticeable when the pigs are driven about; sometimes paroxysmal, but more commonly single, dry, and husky. The skin of the belly, inside the elbows and thighs, and behind the ears is discolored, varying from a pinky red to a dark purple, with, in the case of swine fever, a distinctive eruption which develops into crusts and scabs. Flesh is lost rapidly, the back is arched, and the pig is tucked up and weak; it totters in its walk and often loses the use of its hind legs altogether. The course of the disease varies from three days to three weeks.

In swine plague the lungs being more acutely diseased, the breath is more markedly affected, and the scabs and crusts are not so noticeable.

On opening a pig which has died of swine fever reddish spots will be noticed on the skin and surface of organs like the lungs and stomach. They are absent in swine plague, and occur because the swine fever germs have a habit of clumping together and plugging the small blood vessels, which burst, or the serum oozes through. The spleen is usually enlarged, as are the glands attached to the various organs, especially those of the caul fat (the mesenteric glands), the lining of the chest and belly (pleura and peritoneum) is inflamed and covered with red spots, as are the stomach, bowels, lungs, and kidneys, while in the stomach and bowels clotted blood is frequently found. The real test of swine fever, however, is found in ulcers which occur in the bowels where the small guts enter the large (the ileocæcal) valve. These ulcers vary in size from a pea to half-crown, and are most common in the big gut (the cæcum), that pear-shaped gut which ends in a blind point. They are more or less circular, and project from the surface of the gut with raised and rounded edges, and vary in color from yellow to black according to the time they have been in existence; in very severe cases they actually perforate the bowel, as in human typhoid.

The disease assumes two forms, the acute and chronic. In the former the ulcers are very angry and usually not large, while in the latter they are deeper, but more sluggish in character.

The *post-mortem* appearances in swine plague are distinct from those just described. The ulcers are lacking and the lungs show very characteristic changes. There is a loss of the natural pink color, and patches of them are grey, while here and there appear greyish-black spots called "necrotic areas," which break down into cheesy matter, while there are fibrous deposits on the heart bag and lining of the chest. The throat and bowels are often lined with a so-called croupous deposit, yellowish-white to grey in appearance. In plague the mischief begins in the lungs and spreads to other organs, while in swine fever it begins in the bowels and occurs secondarily in the lungs, &c.

When several pigs die, especially on neighboring farms, one or other of these diseases may be suspected to exist, and no time should be lost in informing the Stock Department, who will decide the matter, and all precautions to prevent spread of infection should be taken, remembering that the disease is spread by men, rats, mice, lice, and other agencies which are not always well under control, while feed and filth are responsible for many an outbreak.

The virulence of swine fever varies greatly from a mortality of 100 per cent. down to less than 20 per cent., and towards the end of an outbreak the majority of animals recover—if a lean stunted growth can be termed recovery—and in addition to never being profitable they may carry the germs for an indefinite time and remain a source of danger.

As the Stock Department determine the method of dealing with affected animals it is not for me to suggest treatment, but more than 20 years of stamping out in England has only resulted in a larger number of pigs being affected now than then; while in countries like Hungary and Holland the almost impossible task of stamping out has been replaced with a preventive, and to some extent curative, treatment of injecting a serum made of extract of dead germs, which greatly modifies the course of the disease and acts as a preventive to in contact pigs. The cost is small, about 6d. a head, and it is carried out by the State veterinary surgeons, and appears to be well-suited to conditions as they exist in South Australia, where herds are more or less isolated, and swine fever does not occur in its more virulent form.

The following mixture, at the rate of one tablespoonful to each 200lbs. of pig once daily, is also recommended as a preventive when the disease is about:—1lb. each of black antimony, charcoal, sulphur, and sulphate of soda; 2lbs. each of bicarbonate and hyposulphite of soda. Thorough disinfection of premises with hot lime to which a little carbolic acid has been added is most desirable, and a tub of disinfectant should be kept to dip boots, etc., in. Isolation and dry housing are also needed, while pigs kept in small lots escape infection more readily.

Burning infected carcasses is preferable to burying, and is not expensive if cross trenches, about 4ft. or 5ft. long and about 9in. deep, are cut out, the earth being thrown into the angles, and wood to get a hot fire going laid on it. The draught runs through the trenches however the wind may be, and the fat of the pig supplies the extra fuel, while wood thrown on top only damps the fire down.

TUBERCULOSIS.

Tuberculosis is the next disease to hold our attention for a few minutes. It is far more important than swine fever, though much less frequently talked or thought about. Its importance may be gauged when the value of pork destroyed on account of it in a recent year in America amounted to roundly £160,000; double that of beef in the same period. The chief danger of the disease lies in its insidious nature. It is seldom noticed during life, while every meat inspector knows how common it is in pork; and, as every pig man's endeavor is to force his pigs along, it is remarkable how, in spite of good feeding, it obtains such a hold in young pigs. These animals are doubly unfortunate, as they contract the form which affects cattle and the human kind with equal facility, forming a link whereby the cattle disease may be transmitted to man and from man to cattle.

The main symptoms are wasting, cough, enlargement of glands, especially those in the neighborhood of the throat, and diarrhœa; but the disease frequently exists to a very marked degree in various parts of the body without any external symptoms being noticed, and this renders the disease doubly dangerous, for it is highly contagious from pig to pig, even if one may dismiss the question whether it is so from pig to man. It renders at least 20 per cent. of the herd among which it makes its appearance ineffective as meat or brood sows, for a sow seldom carries her young successfully when tubercular. It forms a tax that none but a millionaire could afford to pay, and certainly he would not.

Probably the chief sources of contagion are milk and the droppings of affected cattle or pigs, while discarded food from infected human beings is no mean factor in its spread.

Post mortem, the appearances of the disease are in many ways similar to those in cattle. The chief places in the pig where it is found are the lymphatic glands—those kernels which one finds under the tongue and in the meat of the neck, as well as between the lungs above the heart and along the runners between the caul fat layers—as well as in the muscles of the ham and near the tail, those under the tongue and in the neck being the most frequently attacked, for the disease is almost invariably taken in with food, and these outposts of the sanitary corps of the body are the first to fight the enemy.

The changes which occur in the glands are first simply enlargement, then bloodstaining, then small areas of infiltration of the large white cells of the blood, whose duty is to destroy the germs, then little spots or tubercles from which the disease is named, which at first simply break down as mattery points, and later run together, forming a cheesy mass which later changes to a gritty substance, the result of Nature's walling in the enemy. In the earlier stages, as the tubercles break down, colonies of germs escape into the blood stream and attack other places such as the lungs, liver, and spleen, and so the disease becomes generalised.

The risk to men eating tubercular pork the lecturer personally holds to be a very light one; but better authorities than he hold the opposite opinion; but he is heart and soul with them in their endeavors to stamp out the disease, because he knows that profitable as the pig industry may be, it can never, in its palmiest days, stand the impost of 20-100 per cent. deterioration.

Possibly, from an experimental point of view, treatment would be successful and would certainly be interesting; but from a practical side it is out of the question, both from the side of expense as well as on account of its very doubtful success, and with efficient inspection the risk to the consumer would be small and the loss to the owner almost negligible if the carcasses were suitably dealt with as they are in the German Freibank.

ANTHRAX.

Anthrax is the next disease to claim our attention, and fortunately it is not common in South Australia; but should one find one's pigs dying one or two a day, and others seeming seedy with swollen throats, not a moment should be lost in informing the Stock Department, as the disease most commonly shows itself in this way, and frequently an outbreak occurs after the pigs have had a feed of some carcass that has died from an unknown cause. Anthrax is less virulent in the pig than in cattle or sheep, but it is equally dangerous to man if contracted from the pig. If there is the slightest suspicion of the disease, strict precautions should be taken to prevent spread, and anyone who handles pig or carcass should use strong disinfectants on the hands, washing soda being one of the most efficient.

Following these contagious diseases, the management of which is a departmental rather than private matter, we may glance for a few minutes at the various forms of worms which affect pigs, and which are a matter of serious importance, both to the pig and his owner.

WORMS.

Unfortunately, owing to the want of hygiene with which pigs are generally kept, worms are an increasing nuisance, as they are with other stock, and at the risk of being a Jeremiah, the lecturer would again insist on the acute necessity for not neglecting the proper destruction of these pests, which are carried by lice and cockroaches, rats and flies. They may so be spread indefinitely, while their enormously rapid rate of increase practically ensures their survival under conditions the most adverse, namely, cleanliness and care; while we know, only too well, that every condition of ordinary pig-keeping is most admirably adapted to favor their spread.

This is not the occasion, nor were it, would time permit to go into the detail of the life history of the various worms which inhabit the stomach and bowels of the pig; but there are the two common round worms, one like that in man (*Ascaris suis*), the other also about 6in. long (*Echinorhyncus gigas*); the threadworm in the large gut (*Trichocephalus crenatus*); the pin worm, allied somewhat to the blood worms in horses (*Oesophagostomum dentatum*), and scarcely visible to the naked eye; the tiny *Trichina spiralis*;

and a big round worm which prefers the kidney for a home (*Eustrongylus gigas*). All these are rendered less active by the coal tar extracts suggested earlier. Dosing for worms depends, of course, on the age and size of the pigs ; but the following drugs will be found among the more useful :—Castor oil, 1oz. to 4ozs. ; castor seeds, ½oz. to 2ozs. ; pumpkin and melon seeds similarly ; wormseed oil (*Cheopodium*), 5 drops to 10 drops ; chloroform, 20 drops to 60 drops. Once a day is often enough, and all of these will mix with a little milk. They should be given in the morning before the pigs have anything to eat. Turpentine, 20 drops to 30 drops ; and lysol, 20 drops to 30 drops, with a little milk, are often found good also.

Another class of internal parasites is the cystic forms of worms which develop adult forms in other animals ; for instance, hydatids, which also affect man (*Echinococcus veterinorum*), the bladders of which are frequently found in large numbers on the liver and other organs in the pig. Measles, the common name for the cysts of *Cysticercus cellulosae*, minute little sacs which affect the muscles of the tongue, heart, diaphragm, shoulders, and hams, and develop in man into the tape worm (*Taenia solium*) if insufficiently cooked pork is eaten, also affect this animal. A pig affected stands with his shoulders humped up and squeals out of nervous pain if roughly handled ; and if his tongue is looked at by putting a stick in his mouth as a gag the cysts may be seen on the sides of the tongue and cheeks.

The *Trichina spiralis* just mentioned encysts itself in the muscles of the pig, and develops in man some eight or 10 days after eating raw pork, causing extremely painful rheumatic pains in the back and limbs. The worm exists in South Australia ; but, fortunately, raw pork is practically unknown as a food for man ; yet there is a certain amount of risk, as the cysts are so small in pork as to require a microscope to find them.

Treatment of all these cystic parasites is out of the question, and it is false economy to attempt to bring carcasses so affected into use for human food. The Mosaic prohibition of the use of pork was based chiefly on these undesirable conditions.

LICE AND MANGE.

External parasites must claim our attention for a few minutes. They are mange and lice ; but the latter are so big that they are generally called ticks. The general symptoms are irritation and scurfiness in mange with the very apparent presence of the lice in the second condition. They are sometimes so numerous that they appear to be coming out of the eyes and nose. Treatment is best applied by spraying with Cooper's dip on ground that the pigs will not root after because of the poison. Lysol or other coal tar spray may be substituted ; but in either case it is well to rub the pigs over with any cheap machinery oil after drying as this chokes the parasites. A little sulphur may be used as well with advantage ; but all litter must be burnt and the houses well sprayed out with formalin or lysol, preferably hot, and at least 5 per cent. strength. They should then be limewashed with hot lime, to which 1oz. of crude carbolic to the gallon is added. Eczema is sometimes mistaken for mange, and *vice versa*, but as the treatment is the same such a mistake in diagnosis is of little practical importance.

Digestive diseases usually show in swine by diarrhœa or constipation. Either form calls for the correctives mentioned earlier; but if the diarrhœa is persistent some astringent may be required, and may be cheaply and effectively found in chalk or wattlebark, a few ounces of either being given in the feed, or a decoction of wattlebark being mixed, a pint or so, with the slop. Diarrhœa follows sudden change either of food conditions or weather, and must not be neglected in young pigs, which often benefit by a preliminary dose of castor oil. It often takes the specific form of white scour, so fatal to new litters. This is a form of swine plague, and is probably best met by small and frequent doses of lysol in milk, 10 drops to 20 drops, according to age and severity of attack. All discharges must be quickly removed and floors disinfected if one hopes to check the disease. Constipation is best met by a fruit diet (generally obtainable) or Epsom salts. If obstinate in new born pigs, a few drops of glycerine put into the vent will generally cause the bowel to work.

Canker, or sore mouth, often so troublesome in young pigs, and accompanied by blisters and scabs with swelling of the limbs at times, is cheaply and effectively dealt with by putting an ounce of Condy's crystals into a kerosine canful of warm water and dipping the pigs' heads well into it.

Black teeth, that often cause much anxiety, are only a symptom of indigestion which calls for charcoal or ashes in the food.

MUMPS.

Quinsy and throat cough arise from swollen glands in the throat, and are relieved by hot milky food and hot oil rubbed into the swelling outside with a few drops of tincture of belladonna given occasionally. Any such swelling of the throat must be looked on with suspicion, as anthrax or tuberculosis may be the cause.

Breakdown or rheumatism are two convenient terms for covering any form of illness, the diagnosis of which puzzles the owner. The general illhealth, the lameness, loss of condition, and so forth are only symptoms; but in the light of modern knowledge they are symptoms which point to worm trouble and deficiency in substances required by quickly growing animals. The latter is always the case in "thumps," that condition when the beating of the heart can be heard across the yard. The conditions usually yield to vegetable tonics such as quinine, wattlebark, and so forth, especially if a little yeast and molasses are added to the food. Dry and healthy houses are an essential part of the treatment.

Time does not permit of dealing with diseases of sows connected with their special function ; but it may be well to point out that udder ill yields readily to inunctions of warm glycerine or hot soapsuds, neither of which disgust the sucklings.

A fitting close will be a few words on sunstroke, which may be expected after leaving the salubrious air of the hills in the freshness of the morning, and, after a crowded exciting journey, to be chased around the pig yards at Dry Creek without shelter or water during the heat of the day. Treatment must be quick and energetic. Bleed by cutting off the tail, get plenty of cold water briskly on to the body from a strong hose, stimulate the breathing with snuff or powdered tobacco or ammonia in some form or other, and the pig may yet make a carcass that will set.

No attempt has been made to deal exhaustively with the diseases of swine, but the lecturer hopes that, from a farmer's point of view, he has been able to give a hint or two which may enable the owner to avoid dead pig and procure bacon instead.

At the conclusion of the address a number of questions were asked and answered by the lecturer.

Near Bridgewater.

THE WHEAT MARKET.

Prices on the local wheat market firmed slightly during November, but not much activity was shown. As yet but little new grain has been sold, but, judging from reports received, most of that delivered to buyers' agents was of good quality and weight.

Commenting, under date London, October 31st, on the English wheat position, *Beerbohm's Evening Corn Trade List* states—" Whilst most descriptions of wheat, at the commencement of the present week, had declined about 1s. 6d. compared with two months ago, the loss on Manitobas amounted to about 3s. 6d., and the recovery of 1s. to 1s. 3d. may be described as a natural reaction, accentuated by less favorable weather reports from the Argentine and firmer American markets. This week's Argentine cables have been somewhat conflicting, but, although low temperatures have been recorded on two or three days, very little damage appears to have been done so far, and the latest cable states that the weather is warmer and favorable in most districts. The latest reports from Australia describe the crop outlook at the present time as being very promising. Good rains have fallen over practically the whole of the Commonwealth, assuring, with ordinary climatic conditions in the future, a record yield. There is no improvement in the position so far as India is concerned, and a good rainfall is still urgently wanted in many districts.

" Shipments last week were on a large scale, but promise to be appreciably smaller this week. The total exports to Europe in the first three months of the season have amounted to 19,000,000 quarters, against estimated requirements of about 16,500,000 quarters. Stocks in U.K. ports are now 2,300,000 quarters, or the same quantity as on the 1st of August, the excess in imports over requirements being entirely in Continental countries, and in all probability millers there generally hold fair stocks.

" The American markets have been distinctly firmer this week, and prices have advanced 1½c. to 1⅝c. Receipts at Western Points continue on a much smaller scale than at this time last year, and the total since the commencement of the season now shows a fair decrease compared with last year's total, but is considerably larger than in either of the two previous years. The visible supply, which began increasing on a large scale much earlier this year than last, shows a very small increase this week, against a very large increase in the corresponding week of 1912. North American mail advices continue to describe the position of wheat on the other side as more or less an international one, the general opinion being that the course of prices will be mainly governed by the movements on the European markets, which, in their turn promise, especially so far as distant shipments are concerned, to be principally influenced by the progress and results of the Argentine and Australian crops. Still later in the season the crop outlook in India will also have some effect."

Steamer Freights.—(December 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, medium size, Dec.-Feb., 30s. per ton (9⅗d. per bushel), March, 29s. per ton (9⅕d. per bushel); to South Africa, 27s. 6d. per ton (8$\frac{9}{10}$d. per bushel), prompt or new season. Parcels, Port Adelaide to London-Liverpool, or Continent, 27s. 6d. per ton (8$\frac{9}{10}$d. per bushel); Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel); to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 30s. per ton (9⅗d. per bushel), new crop; South Africa, 25s. to 26s. 3d. per ton (8d. to 8⅗d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on December 1st—

Butter Factory.—The supply of cream received last month was larger than that received in October, was of excellent quality, and the sales were proportionately large. Prices varied very slightly during the month, rates at the end of the month being superfine, 1s. 1d.; pure creamery, 1s. There is every prospect of a slight rise shortly.

A. W. Sandford & Co., Limited, report on December 1st—

Butter.—Quantities of cream and butter further increased last month, and for top grades values maintained firm, best factory and creamery, fresh in prints, selling at 11d. to 1s. 1d. per lb. In other lines, however, prices are a little easier, separators and dairies selling at 9½d. to 10½d. per lb.; store and collectors' lines, 7¾d. to 8½d. per lb.

Eggs. Large supplies came forward, but under the influence of a steady demand, rates held with but little alteration. Quotations—Hen, 8½d. per dozen; duck, 9½d.

Cheese – The month's trade was a very heavy one indeed, record quantities arriving. Prices eased somewhat, though with inter-State markets operating, good clearances were effected. Present quotations, 5¼d. to 5¾d. for large to loaf.

Honey.—Last season's take of prime samples are practically cleared, and buyers are waiting the new season's, which may be expected shortly. Present price for prime clear extracted, 3¼d. per lb.

Almonds – Stocks are exhausted, and already quotations are being asked for the new crop. Brandis, 6¼d.; mixed soft-shells, 5¾d.; hard-shells, 3d.; kernels, 1s. 6d. per lb.

Bacon.—Values show very little alteration for the month, the scarcity of the live hog and consequent high prices somewhat affecting sales in this line. Hams are in good demand, the trade purchasing in anticipation of Christmas. Best factory-cured sides, 10d. to 11d. per lb.; hams, 1s to 1s. 2d. per lb.; well cut and cured farm middles and rolls, 8d. to 10d.; country hams, 9d. to 11d per lb.

Live Poultry. – Consignors throughout the month realised very satisfactory prices for all classes where quality was right, and good rates are likely to rule from now on, as buyers are purchasing extensively in anticipation of the Christmas wants. Good table roosters brought 3s 3d. to 3s. 9d. each; nice conditioned cockerels, 2s. to 2s. 6d.; hens and light cockerels, 1s. 9d. to 2s 3d.; ducks, 2s. 3d. to 3s. 8d.; geese, 5s. to 5s. 6d.; pigeons, 9d.; turkeys, from 9d. to 11d. per lb. live weight for fair to good table birds.

Potatoes and Onions. –The Adelaide market is now drawing practically the whole of its potato requirements from local sources. Supplies are plentiful and moderate prices seem assured. Onions—There has been a little difficulty recently in getting new onions suitably dried for long distance trading, but the warm weather now setting in will speedily correct this trouble. Local crops are good, and as reports from Victoria indicate a heavy yield, high prices appear to be out of the question. Present quotations – Potatoes, Gambiers, £5 10s. to £6 per ton on rails Mile End; 5s. per cwt. in the market. Onions—Gambiers, £8 10s. to £9 per ton on rails Mile End; 8s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of November, 1913, also the average precipitation to the end of November, and the average annual rainfall.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

January 14th and February 11th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

WIRRABARA (Average annual rainfall, 18·91in.).

November 15th.—Present: 24 members.

Hay-Making.—In a paper under this heading Mr. E. Hollett advised farmers to have everything in readiness before commencing their hay-harvesting. The hay should be stooked close behind the binder, which would prevent it becoming bleached. Good wheats for hay were Lotts, Baroota Wonder, Yandilla King, and Silver King. However, if the farmer chaffed his hay it was a better policy to grow wheats which were suitable for grain. The crop should not be cut until the flag at the bottom of the straw had dried off. The stack should be built on a floor of solid timber or straw; hollow timber provided a harbor for mice, &c. The round-cornered stack was best. It should be kept fairly full in the middle. He preferred building a false roof, starting a short distance in from the edge of the stack, *i.e.*, about the length of one sheaf, and filling the centre well. A start should then be made at the outside of the eaves with the roof, the best sheaves, head outwards, being used. After harvest a protecting covering of straw should be put on the stack. Members favorably mentioned roofing with galvanized iron fixed with specially made screws; this was very simple and effective.

WILMINGTON, November 12th.—It was decided that the Branch should conduct experimental wheat plots on the lines suggested by the committee appointed by the Congress to consider the matter of practical work for the Bureau.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

BEETALOO VALLEY (Average annual rainfall, 18in. to 19in.).

October 20th—Present: seven members and three visitors.

Marketing Produce.—Mr. J. Joyce contributed a paper on this subject, in which he stated that produce must be placed on the market in good condition and in an attractive package if it was to command the best prices. An inferior article tastefully presented would often obtain a more ready sale than a superior article poorly marketed. Wool for market should be free from dirt, grass seeds, &c. The presence of this might mean a loss of ½d. or ¼d. per pound. A large amount of dirty wheat was marketed, especially, he thought, since the introduction of the harvester.

Breeding Lambs for Market.—Mr. A. Woolford contributed a paper on this subject, in which he advocated obtaining young Merino ewes, say four-tooth, of good frame and crossing them with a Shropshire ram. If the ewes lambed early, say in April, with good feed the lambs should be ready for the early markets. From this cross big lambs with good wool should be obtained which should do well and fatten quickly. He had found this district very suitable for sheep. There was a good average rainfall and a good supply of grass, which kept green nearly all the year. The locality was also suitable for wool-growing, the wool being heavy and greasy. He advised growing lucerne for topping off. Cattle were not so profitable as sheep. Mr. F. Bartrum considered this district unsuitable for lamb-raising, as the holdings were too small and feed was always late. With regard to the quality of the wool grown Mr. Murphy stated that his experience had shown it to be very fine and free from grease. He recommended sowing barley for early feed for ewes and lambs, which would easily repay the expense of the crop.

GLADSTONE (Average annual rainfall, 16in.).

November 15th.—Present: 19 members and four visitors.

Dairying.—Mr. R. A. Humphris read a paper. With the closer settlement of the Murray Flats, he said, there seemed to be a reviving interest in dairying. The dairyman was advised to provide ensilage and stacked fodder for use in the winter months or in dry seasons. Iron milking sheds, with cement floors and fitted with bails, were best. A milking machine and separator were necessary, and a Babcock tester should complete the plant. He preferred the Shorthorn cows, as they made better beef when they had served their purpose as milkers, than the lighter breeds. The Holstein was the best milk producer. Good milk lines, broad hips, wedge-shaped body, tapering to a fine thin head, fine horn and tail, well-set udder and quarters were indications of quality in a cow. The practice of testing the herd was strongly recommended, and the method of carrying this out explained. Pigs should be kept and calves fattened. A few veterinary appliances, such as a milk fever outfit, should always be on hand.

NORTH BOOBOROWIE (Average annual rainfall, 16·35in.).

October 16th.—Present: 14 members and two visitors.

Poultry Breeding and Rearing.—Mr. W. F. Hannaford read a paper on this subject, as follows:—"Having decided to keep poultry, our first consideration should be housing. It is not necessary to build an elaborate house. It should be warm, dry, free from draughts, but allow of plenty of fresh air. A good serviceable one can be built of wood and galvanized iron, the size being about 10ft. long, 8ft. wide, and 5ft. 6in. high in front and 6ft. at the back. The back and sides should be enclosed with small-fluted iron, the roof of the same material, with one sheet along the front lengthways; the remainder should be enclosed with wire netting. The perches should be from 12in. to 18in. from the ground and movable for convenience in cleaning. All timber should be tarred to keep out vermin. I would strongly recommend using only pure-bred typical male birds. It may not be possible for one to have all pure to start with, but the males should not only be pure but the best that one can afford to buy. While admitting that some great records have been put up by White Leghorns, I wish to point out that some very low figures have been made by the same variety. Take, for instance, the present competition. The leading pen of White Leghorns have laid 764 eggs, while the lowest pen of White Leghorns have only laid 330 eggs. It is not the breed so much as the 'strain' that one must look to when buying. At the same competition we find Black Orpingtons have laid 700 eggs and Silver Wyandottes 565 eggs. I therefore advocate the dual purpose fowl that will lay a fair number of eggs during the year, rear a clutch of chickens if required to do so, and when it has served its purpose on the farm make a good joint when placed on the table, or give a payable return when sent to market. I have decided to keep Black Orpingtons of an approved strain, with Silver Wyandottes as my second choice. The morning meal should consist of boiled scraps from the house thickened with pollard. All birds confined to pens should receive finely-chopped green stuff at mid-day, and at evening good sound grain should be scattered in straw or some other litter. Fresh water must always be available. For heavy breeds the best time to hatch is the latter end of August up till September and the early part of October. Pullets hatched during that period will lay in time to catch the Lenten season and before the cold weather sets in, and should lay all through the winter, thus catching the best markets. If hatched too early they will moult in the autumn and may not lay through the cold months. I prefer putting eggs under a hen for 18 or 19 days, then removing them into an incubator to complete the hatch, rearing the chicks in the brooder. Hand-reared chicks do better and are more docile. If hatching under hens one must be careful to see that the broodies are free from vermin and scaley legs, or there will be trouble with the young stock. Another method of hatching is by means of the incubator entirely, and each maker supplies full directions with each machine. For the first week the chicks should be fed on hard-boiled eggs and bread crumbs. The second week they may have fine cracked grain, the size being gradually increased as the chicks come on. If they are reared in a brooder it must be cleaned and well aired daily and plenty of fine chopped green feed and good grit must be supplied each day. If the females run at large a pen with a house attached should be erected in which to place the male birds when the breeding season is over, and also to put the cockerels in as soon as they begin to crow. The hens and pullets will lay quite as well alone, and infertile eggs keep better. The cockerels will fatten better when confined, and will realise better prices than when allowed to roam at large. In this locality, where the holdings are small and lucerne or other fodders can be grown successfully, poultry-breeding must play a very important part on our farms. Our revenue for the year can be greatly increased if we pay the attention to our fowls which they deserve." Members generally agreed with the ideas expressed in the paper. Some, in order to secure eggs the whole year round, made a practice of hatching chickens in the autumn as well as in the spring.

PORT GERMEIN (Average annual rainfall, 12·84in.).

October 18th.—Present: 11 members and four visitors.

Feed for Stock.—Mr. Holman contributed a paper. In this district, in an ordinary season, he said, a landholder might run a number of sheep or cattle sufficient for the carrying capacity of his land, but in a wet and early season the same number would be useless to keep down even the weeds on his fallow. Farmers have been blamed for neglecting to conserve fodder in seasons of plenty, but the requirements of the ordinary working stock during a period of drought extending over, say, three years would tax to the utmost all provision in this regard. It was profitable to purchase growing cattle of one or two years of age, as their value increased even if they were not fattening. He doubted whether sheep would pay as well as cattle, as dogs were troublesome in the Flinders Range. In the discussion which followed Mr. Hacket said fodder could not be conserved in these dry areas and feed could not be left in the paddocks. Mr. Carmichael mentioned that stacks of cocky chaff and straw were at one time plentiful, but now there were few stacks of hay, even in favored districts. Several members thought farmers had been improvident in this regard.

Cows *v.* Sheep on the Farm.—In a paper on this subject Mr. Stone favored sheep, as they were less trouble. Where suitable labor was available cows could be kept at a profit. The milk should be weighed and tested, and the unprofitable animals culled out. He would not keep a cow of more than 8 years of age, as after that the milk yield and the percentage of butter fat decreased. He preferred the Merino sheep, which were less troublesome with the fences. They were hardy and capable of withstanding a dry season. Sheep were of great value in cleaning fallow, especially of oats and mustard. Messrs. N. Ragless and Hillam preferred crossbreds for lambs and Merinos for wool.

GEORGETOWN, November 13th.—Marketing Wheat.—Mr. Page read a short paper under this heading He advised farmers not to accept storage notes for their wheat, but to sell it outright, and thus ensure competition.

NORTH BUNDALEER, November 12th.—Preparations for Harvest.—Mr. J Scriven read a short paper advising members to overhaul their harvesting machinery at such time as to obviate delay when the harvest was ready. The estimated requirement of cornsacks should be ordered as early as possible.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

JULIA (Average annual rainfall, 18in. to 19in.).

October 11th.—Present: 16 members and 18 visitors.

Parturient Apoplexy, or Paralysis.—In an interesting and instructive paper on this subject, a visitor explained that this disease only attacked milk cows, those most subject to the trouble being heavy milkers in a high state of nutrition. The disease usually appeared within 24 hours after parturition, generally following an easy birth. At the outset the affected animal manifested uneasiness, moved about in a restless manner, struck at the abdomen with its hind legs, probably bellowed, ground the teeth, with possibly spasms of groups of muscles, or even a general convulsion. After these, the cow showed weakness, staggered, and fell. As the paralysis advanced, it stretched on its side on the ground, usually with the neck bent to one side, bringing the nose into the flank or costal region. The animal was in a state of partial or complete unconsciousness

Digestion was arrested, fermentation sets in, and the beast became affected with flatulency The contents of the rectum and colon were hard and dry, and might be covered with mucous or blood. The animal was unable to pass the urine, the pulse was small, often imperceptible. Without treatment the disease usually ran rapidly to a fatal issue. It was necessary to carefully distinguish between this trouble and anti-partum paralysis, and broken back. Preventive treatment consisted of moderate feeding, especially of grain, in the later stages of gestation. The bowels should be kept in good condition by the administration of magnesium sulphate, sodium chloride, and sodium bicarbonate. The afterbirth should be removed soon after parturition, and an injection given. The curative treatment recommended by Schmidt consisted of the thorough disinfecting of the hands of the operator and the udder and teats of the cow by washing with a 5 per cent. solution of carbolic acid, or 1½ per cent. of lysol. The apparatus, consisting of a small glass or nickel funnel and a rubber hose, should be sterilized immediately before it was used. The tube should be inserted into the teat, and a continuous flow of sterilized air pumped into the udder. After the quarter was well distended the tube should be withdrawn, and the teat tightly tied with a piece of tape, to prevent the escape of the air. The udder should then be gently massaged upwards towards the body. The tapes should be removed two hours after the cow was on her feet, the air and milk being milked out 24 hours afterwards, if recovery were assured. The animal should be without feed for this time, and should then be given only small quantities at a time. Lukewarm water only should be allowed. The urine should be removed with the catheter at intervals until this procedure became unnecessary. As the animal was generally unable to swallow, it was dangerous to attempt to administer medicine through the mouth. One ounce to 1½ozs. of aloes might be given through a probang inserted into the stomach. Rectal injections, consisting of linseed oil, cotton seed oil, or warm soap solution were necessary at intervals. The animal should be propped up and thickly covered with blankets and straw If improvement were not marked within eight hours, the treatment should be repeated. The paper then described cases where the writer had successfully carried out the treatment recommended.

MALLALA (Average annual rainfall, 16·88in.).

November 3rd.—Present: 11 members and two visitors.

Roseworthy Agricultural College.—On October 27th, 12 members and 11 visitors journeyed to the Agricultural College, Roseworthy. A comprehensive inspection of the institution was made, and the visitors were much impressed with the work being done there.

Pea-Growing.—Mr. J. J. McCabe read a paper on this subject. It was necessary, he said, to keep sheep for the purpose of cleaning the fallow, and he advocated growing this crop to tide the animals over the summer months, when feed was scarce. He had sown 16 acres with barley the previous year and had fed it off bare. He ploughed it with the first rains of the season, then harrowed and allowed it to lie out until after seeding. He cultivated the land to the depth that it was ploughed, after a good rain in August and drilled in the peas at the rate of a bushel to the acre, 100lbs. of super. being applied; he then harrowed the land again. The crop was too thin and did not mature properly. He raked up a few small wagon loads in the first week in January and obtained four bags of peas; eight cows and 150 ewes were then turned in. The cows were taken out after two weeks but the ewes remained until March, when the paddock was as clean as fallow land. The sheep were in prime condition. Oats which had been sown on this land looked as well as those on fallow. In reply to questions Mr. McCabe said that 2bush. was the best quantity of peas to sow to the acre, and 100lbs. of manure should be applied. He would sow about the middle of June. It was not necessary to roll the crop unless it was intended to gather the peas. Several members had tried this crop this season for the first time.

NANTAWARRA (Average annual rainfall, 15·90in.).

November 13th.—Present: seven members.

Fodders.—Mr. A. F. Herbert read a paper. A stack of straw, preferably oat or barley, sprinkled with salt, he said, was a valuable standby in case of shortage of feed. Mixed with a little crushed grain, this would even make a suitable feed for working stock. Chaffed pea straw also was good. Pigs and sheep did well on the peas. Early sown barley provided a good supply of greenfeed as well as grain if properly managed. Algerian oats drilled in early with super. on stubble, cultivated, then harrowed after the drill, yielded good feed. The farmer who had an engine was advised to procure a small header, bind portion of his crop, and after threshing, stack the straw. Young horses and cattle would thrive on this, especially if it were chaffed. Cocky chaff, also, was not to be despised. Mr. Sleep agreed with the remarks of the writer of the paper. Mr. Smith recommended sprinkling straw that was being stacked with a solution of salt and water. Algerian oats should be sown on stubble land worked with the cultivator. Cocky chaff was not worth saving. Mr. Sutton strongly advised stacking straw. A stack he had cut with the binder had been disposed of at a very satisfactory price. He had planted a small area with peas and turned the stock in. The peas still continued to grow, and some must have matured, as each year plants appeared. He had tried dry salt on straw with indifferent success, but when the salt had been applied in a damp state it had all been absorbed. Mr. R. D. Nicholls thought cocky chaff well repaid the extra trouble expended in obtaining it. He favored growing peas, and had found that pigs and stock were partial to and did well on them. Horses required a certain amount of bulk food, therefore the feeding of too highly concentrated food should be avoided. In reply to questions Mr. Herbert stated that crushed oats were more easily digested than whole. They mixed well with the feed and adhered to the chaff. He had not noticed a great difference between the Algerian and Calcutta Cape oats, but had sown Algerian for several years with thoroughly satisfactory results.

NORTHFIELD (Average annual rainfall, 19in.).

November 4th.—Present: Seven members and one visitor.

Farm Management.—Mr. J. Williams read a paper. The farmer needed a good knowledge of sheep, he said, as these were indispensable on the farm. He preferred the Merino ewe, if of large frame, because of its fleece, and as, if mated with a Shropshire ram, it would produce a fair export lamb. The Merino-Lincoln first cross ewe produced a less valuable fleece, but this was made up for in the value of the lamb when she was mated with either a Shropshire, Southdown, or Dorset Horn ram. The Border Leicester ewe produced a good fleece, and when crossed with a Shropshire ram yielded a first quality lamb. The sheep helped to keep the land clean, and improved it by their droppings. No farmer should be without two or three dairy cows. The Jersey-Milking-Shorthorn cross was the most profitable. They produced large quantities of rich milk, were hardy and could be fattened for beef. The calves also sold well for veal. The Clydesdale was the best horse for the farm. Generally, early fallow, well worked, was the safest method of cultivation. The ploughing should be deep and subsequent working shallow

TWO WELLS (Average annual rainfall, 16·36in.).

November 15th.—Present: 14 members and one visitor.

Petrol and Oil Engine.—Mr. L. H. Dawkins read a paper. Farmers were not acting wisely, he said, in buying petrol engines, as their management required greater skill than that necessary for the oil engine. Petrol was more expensive than oil, the petrol engine was more complicated in construction, and the number of revolutions per minute was greater than in the case of the oil engine. The engine purchased should always be capable of easily performing the work required of it. With oil engines trouble was generally due to starting the engine before it was thoroughly heated, or neglecting to clean the vapouriser. The oil engine ran more smoothly, had larger bearings, crank, and a longer piston than the petrol engine. Mr. R. Kenner thought the majority of petrol engines simple to manage. A reserve power was always necessary. Mr. A. J. Baker mentioned the danger of fire with oil engines. Members generally favored the petrol-driven engine

YORKE PENINSULA DISTRICT.

ARTHURTON (Average annual rainfall, 16in. to 17in.).

November 5th.—Present: 12 members.

Harvest Prospects.—An inspection of crops in the district had revealed a remarkable change for the better during the past few weeks.

Fallow.—Mr. T. H. Howlett read a paper, in which he said the farmer should observe variations in the nature of soil on the farm and adjust his methods of cultivation accordingly. For fallowing land for grain crops he preferred summer working, which would loosen the surface and encourage the germination of weed seeds. Immediately seeding operations were completed the fallow, if heavy land, should be ploughed to a depth of 3in. or 4in. and harrowed as soon as possible, across the ploughing for preference. After the first working the mouldboard plough should be kept out of the fallow. In loose rubble or sandy soils the cultivators could be used. The harrows should be put over the ground after rain, and sheep should be used to keep the weeds down. In the event of the surface still being rough and lumpy in places it should be broken down with a land roller and harrowed immediately. When there was a great deal of fallow to be gone over in a limited time a heavy set of harrows would be found very serviceable. On several occasions he had noticed land ploughed in March or April and cropped with an early variety of wheat had yielded 20bush. per acre, whilst bare fallow had yielded 25bush. In his opinion the former was the more profitable, as the cost of working was considerably less, and the landholder could carry a greater number of sheep. Autumn fallow greatly reduced the danger of drift in light soils. If oats and barley were drilled into this class of soil immediately after a wheat crop, and the crops were heavily fed off by stock, the fertility of the soil would be greatly improved. Barley was preferable to oats, as stock took to it more readily, and it gave much more feed in the winter months. His experience was that it did not impoverish the soil for the wheat crop following. Experiments should be conducted with the object of determining the fodders which would yield the most summer feed for sheep. Unproductive patches of soil should be analysed to determine the constituent which was lacking in quantity. Different manures should be tried. Mr. Short advocated the use of the roller for packing the soil. The Hon. Secretary concurred, but also recommended the frequent use of the harrows.

MAITLAND (Average annual rainfall, 20·08in.).

November 1st.—Present: 10 members.

FALLOWING.—The Hon. Secretary read a paper on this subject, in which he said that the principal reason for fallowing was to conserve moisture. At the same time rubbish, which was plentiful in this district, was destroyed. Land to be fallowed should be turned up as early as possible in the season in order to get the benefit of early rains. He favored shallow ploughing for the first working, as the land worked down much finer and weed seed was not buried too deeply. Under ordinary conditions and average rainfall, when the farmer had completed the first working that on which he had commenced would be ready for the second cultivation. Following this the land should be gone over with harrows that would leave the surface as smooth as possible. Rubbish grew much better when the surface was well worked down, provided the seed was not buried too deep. This should be fed off to sheep and the land ploughed again. In this district fallowing should not exceed a depth of 3in. About the first week in October the land should be harrowed crosswise to the ploughing with heavy harrows. This would discourage the appearance of strips of a green tinge in the paddocks, caused by rain falling while the ploughing back was in progress. The shallower the land was worked the less these would be noticed, as the rubbish dried up more quickly. After this, under ordinary conditions, the first paddock ploughed would be ready for the third working. The land should be harrowed again if possible. If rain fell during the summer it should be ploughed as soon as harvesting was completed. In the absence of rain, however, working with weighted harrows would be of value. He asserted that well-worked fallow in an ordinary season conserved moisture equal to 3in. of rain. When seeding the depth of working should not exceed 2in., as the land was fairly free and there was a tendency for the seed to go in too deep. He would use a plough of not less than 10 furrows. If the working were done shallow at first and the depth gradually increased one horse to each furrow would do the work fairly comfortably. For shallow working he preferred a plough that cut a narrow furrow, say, not more than 7in. More furrows were better than an over-wide cut. Members generally agreed with the writer of the paper.

MINLATON (Average annual rainfall, 17·46in.).

October 18th.—Present: 11 members.

FALLOWING.—In a paper on this subject Mr. S. Vanstone said that land should not be ploughed when dry and hard if this could possibly be avoided. It required more horse power and extra labor to work it down to a fine seed bed. On the other hand if well soaked the soil would work down finely and moisture was easily retained. It was a mistake when ploughing to turn the soil out toward the fence each time and thus create an unsightly bank. During the first round it was advisable to keep the fence about eight yards distant on the left hand side, and afterwards reverse the direction, leaving the narrow strip near the fence until last. When the land was ploughed again it should be turned toward the fence from the start. For land clear of straw or rubbish he preferred a plough cutting not more than 6in. furrows. An eight-furrow plough with a 6in. cut worked the land much better than a six-furrow plough with an 8in. cut, and the draught was no greater. The very light soils in this district were not improved by deep ploughing, and it was not advisable to work the land to the same depth each year. The headlands should be turned outwards the first ploughing and inwards the second. This tended to keep the surface more even. It should be harrowed as soon as possible after ploughing. Land fallowed early in the season, say in June or July, was much benefited by frequent harrowings, and if the weeds could be kept down only harrowing would be required until seeding. Fallow should only be worked deep enough to kill the weeds. In this district the last ploughing before the summer should be from east to west, as the north winds might otherwise cause drift. In the discussion which followed members advocated burning off grass or rubbish on land to be fallowed the following winter, as this practice tended to discourage the development and spread of takeall. Members generally advocated frequent harrowing.

Homestead Meeting.—This meeting was held at the homestead of Mr. J. Martin. Members inspected the crops, which were looking well and had benefited greatly by the recent rains. The stables, chaff and engine rooms were also inspected.

WESTERN DISTRICT.

COORABIE (Average annual rainfall, 11in. to 12in.).

October 11th.—Present: 16 members and 10 visitors.

The Farm Employee.—Mr. V. R. Weston read a paper, in which he said—"In a district like our own it is, in the average season, difficult to obtain suitable labor at an average wage, but I am sure that with attention to the welfare of those we employ we will not only keep the good employés we have but will in time have a bigger supply. Even though we may not have a surplus of men, we cannot be too particular of those we employ. If we only employ the best, then only the best men will apply for employment. In my mind the man we want is he who works, not merely for the sake of earning a living, but who has for his object that of ultimately becoming an employer himself. This class of man is the ideal. He takes more interest in his work and in doing it well, and shows more consideration toward his employer than the man who is merely after his wages. Personally, I would sooner do without a man than have to employ a second-rater. It is indeed poor economy to employ one of these merely because we can get him for a lower wage than a tip-top man, and is something like purchasing an inferior article because it is cheaper than the best, but in the long run it proves the dearest; for this class of man seldom, if ever, takes an interest in his work. There is rather a tendency among some farmers to think that because a man is in their employ he is not entitled to the comforts which he himself enjoys. Perhaps he is not; yet, to my mind, a comfortable home is more likely to produce a feeling in the man that he should do all he could to his employer's interest than otherwise. One cannot, of course, lay down any set hours for work, but in the slack season 8 to 12 hours, according to the length of the days, is long enough; but, of course, during seeding, hay-making, and harvesting operations hours must of a necessity be longer. but I do not think there is any necessity for so-called night work, with the exception of feeding up, and instances where the man has a long trip, such as wheat-carting to port and the return home. I also maintain that during those working hours the employé should be kept going and not allowed time to think of what he is going to be told to do next; for I am certain that idleness is the parent of discontent. There are many ways in which the farmer can make things rather more congenial for his employé, and my previous mention of wheat-carting and similar road work suggested many little points to my mind. For instance, if when the man gets home with the team he has some one to help him unharness, feed, and water them. it will naturally make him feel that his employer has at least a little consideration for him after his tiring work of the road. Then I do not think that an employer should expect his men to do work which, if their positions were reversed, he would not do himself. For instance, after a man has been on the drill or plough all day is it fair to expect him to go on pickling wheat after tea? I do not think so; and yet have repeatedly seen this done, Of course there are exceptions where the employé does not mind doing it, but they are very rare. When an employé makes an error in his work, or fails to do some job which he should have done, do not put off reproval until he repeats his error, but correct him there and then, not in a blustering manner, but quietly show him his mistake and how to rectify it. Then he will know what to do should similar circumstances arise again. It is hard at times for the farmer to keep his temper, but a little of the give and take principle and some consideration for the other man makes things work far more smoothly. In conclusion, I make one suggestion, and that is 'treat your employés well, and they, if they are the class of man you want, will treat you equally well.' " Members thought an occasional Saturday afternoon holiday would go a long way in the direction of maintaining amicable relations between the employer and employé. The farm laborer to-day required a certain amount of experience with machinery. Generally the views of the writer were agreed with.

GREEN PATCH (Average annual rainfall, 26·56in.).

November 10th.—Present: 10 members.

Currants and Pears.—In presenting a report of the Annual Congress Mr. Sage mentioned that as the Australian market for Zante currants had been glutted growers were not now planting this vine. Several growers had made the mistake in planting pears of confining their attention to one or two kinds; as these had not been self-fertilising, poor crops were the result. This fruit did splendidly in this district.

Harvesting Hay and Grain.—Mr. C. Parker contributed a paper on this subject, in which he said that in the event of breakages in machinery not receiving immediate attention a "repairs book" should be kept, in which a note should be made of points requiring attention. His experience had led him to the conclusion that oats for hay should be cut well on the ripe side—when they were a bright amber color. Stooking should follow directly after the binder, the sheaves being placed in long rows four sheaves wide. Hay for market, however, might need to be cut earlier; it was necessary to meet the wishes of the buyer in this regard. In hot weather, with drying winds, from 12 to 15 days was long enough to leave the hay in the stooks; but if the weather were dull and cloudy, without winds, it should remain in the stooks for about three weeks. A good method of determining whether it was sufficiently matured was to extract two or three straws from the centre of the sheaf; if the node had lost its moisture the hay could be stacked with safety. Wheaten hay could be treated in a similar manner, but it should be cut from six to 10 days earlier than oats. On no account should the sheaves be laid flat on the ground, as the hay was likely to be damaged by dampness from the ground. Grain should not be stripped until it was thoroughly ripe and well set. He favored the use of the stripper, especially in this district, where the cocky chaff was so valuable for winter feeding. The motor winnower was most economical when the area to be dealt with was large. The wheat should be marketed in a clean condition. Members thought that until the present system of marketing wheat was altered it would not pay them to make any special effort to produce a clean sample.

GOODE (Average annual rainfall, 12in. to 13in.).

October 16th.—Present: 11 members and four visitors.

Red Rust.—A short paper on this subject was read by Mr. L. V. Hughes. Some years ago he had crops of Federation and Carmichael's Eclipse growing side by side. The former was practically destroyed by rust, whilst the latter was unaffected. This year exactly the reverse was happening. He had noticed that a crop on ground on which the stubble had not been burnt showed signs of rust three weeks earlier than that where the stubble had been destroyed by burning. He was of the opinion that dressings of manure, by encouraging rank growth, were responsible in a large measure for the trouble. Red sandy soil seemed more likely to carry affected crops than titree land, whilst King's Early and Gluyas wheats appeared to withstand the disease better than the later varieties. The Hon. Secretary thought Gluyas the nearest approach to a rust-resisting wheat. Mr. L. Will advised members to select from the crops any heads that were free of rust and plant these for seed.

KOPPIO (Average annual rainfall, 22·40in.).

October 15th.—Present: eight members and two visitors.

The Get-up of Wool Clips.—Mr. W. R. Richardson read a paper, in which he said—"If wool were sold in the same way as wheat there would be no inducement for growers to take trouble in getting up the clip; but as wool is sold at auction and is carefully gone over by the buyers before the sale, the better article is bound to bring the higher price. A fleece is made up of different qualities of wool. For instance, the belly wool is not equal in quality to that from the shoulders and ribs. Again, the wool on the breech is often coarse and of poor quality, and if all this with dirty locks is bundled together we cannot expect the best of the fleece wool to command the price it should. The buyers, if they come across a carelessly got up clip, will always keep on the safe side and rather buy on the lower quality wool than try to average it up and give the price it is worth. The speculative local scourers are always on the lookout for any cheap lots, and a carelessly got up clip is just what they desire. The buyer is very much rushed in valuing the wool before the big sales, and cannot waste time in pulling out a whole lot of wool from the bale to find out exactly what it contains. He will value on what he first pulls, and it is for us to put the wool before him in lots most likely to suit him. The buyers are out here every year, and if they find that a clip of a certain brand has not been honestly got up they will very soon fight shy of that particular brand: but if, on the other hand, they find a brand is always carefully put together they will be on the lookout for it, and will be able to give the best price, simply because they have confidence in it. To get up a clip from a flock of, say, 500 or 600 sheep I should recommend the following:—First, have a perfectly clean floor on which to do the shearing. This must be kept clean, as dirt mixed with the fleece will at once take off that beautiful white lustre that bright clean wool has. For a flock of this size there is not much actual classing required, and any intelligent man who knows anything about wool can do all that is necessary. It is a mistake to make numerous small lots, as they do not command the attention that the larger ones do. I would therefore only make two lots of fleece, and the second lot should only consist of the dirty yellow fleeces or any that would spoil the look of the first lot, perhaps only making a bale or two. If a very broken fleece comes on the table it is best to tear it up and put it with the pieces. The bellies should be picked up as they are taken off and kept separate, and the stained pizzle pieces in the wether bellies should be taken out and put in with the locks. In skirting the fleece only take off the dirty edges and any pieces filled with grass seeds. Sometimes the breech wool is inclined to be coarse and matted, and if so it is as well to take it off. The skirts should be put somewhere separate to be dealt with later. After skirting the sides of the fleece should be doubled over towards the middle and it should be carefully rolled from the breech to the shoulder. We have then different lots of first and second fleece, pieces, bellies, and locks. It is as well to pick the pieces over, as very often in the hurry of skirting dirty pieces get in. These can either be put with the locks or, if sufficient, made into a separate lot and called second pieces. Care should be taken in sewing the bales and branding to make a neat job. The branding should be done in good large print, both on top and on the front of the bale. Brand first fleece, AA combing; second fleece, A combing; first pieces, AA pieces; second pieces, A pieces. I am certain that a properly got up clip will pay handsomely for the trouble taken." In the discussion members agreed that if proper care was exercised the grower benefited. Mr. Newell thought that much good wool was wasted through skirting too deeply, and he also suggested that the question of growers being allowed something for their woolpacks should be brought before Congress next year. Mr. Gardner was of the opinion that it paid the grower to keep the different types of wool separate.

MANGALO (Average annual rainfall, 14in. to 15in.).

October 18th.—Present: 10 members and six visitors.

DISCUSSION.—The following subjects were introduced for discussion at this meeting:—

Marketing of Wheat.—Members considered that the system under which wheat was sold was unjust. The farmer who cleaned his wheat well and obtained a good sample received no more per bushel than those who sold dirty and inferior grain. It was decided to inquire from the various wheat merchants if they would be prepared to give higher prices for well-cleaned samples of high grade wheat.

Spring v. *Bridle Draught Ploughs.*—Members generally agreed that the spring draught ploughs were more suitable than the bridle draught implements for use in hilly country.

Hay-Making.—It was generally thought by members that sheaves should be left half a day before stooking, and from 30 to 45 sheaves should be put into a stook. It should be left 12 to 16 days before carting. The best method of building a stack was to keep the sides plumb, the ends being rounded. The outside sheaves should be placed butts outwards, the heads of the second row being placed out as far as the bands of the outside sheaves, and so on. The centre of the stack should always be kept from 12in. to 8in. higher than the outside, and the roof commenced well over the walls, with the butts outwards and a good slope. Some members, however, recommended placing the heads outwards, as rain ran off better. Mr. Burton, sen. (a visitor), gave some practical hints regarding the building of haystacks.

MILTALIE (Average annual rainfall, 14·55in.).

October 11th.—Present: six members and three visitors.

Care of Horses.—In a paper on this subject Mr. H. Brine said that to ensure the best results too much care could not be taken of the horses on the farm. Working horses should receive four good feeds a day, consisting of a fair-sized dish of chaff and a liberal supply of bran. Too much whole grain should not be given, because of its heating propensities, which tended to cause sore shoulders. For the fourth feed no grist was necessary, enough chaff only being given to create an appetite for the morning feed. Small feeds given regularly were best. The practice of putting enough feed in the manger for the night and morning feeds in order to save time in the morning, was condemned. Each horse should have its own stall, and should be taught to use it. All stalls should be kept thoroughly clean. The animals should not be tied up at night, as they would not secure the necessary exercise or rest, but should be enclosed in a spacious yard containing a straw stack. Each animal should have a well-fitting collar, hames, and winkers. The leather should be kept clean and soft with neatsfoot and castor oils in equal proportions. It should be oiled at least twice a year. Collars should be brushed each morning to remove sweat streaks and caked hair. The horses also should be well groomed each morning. He would not break in foals until they were 2½ years of age, and would then give them light work only until after they were 3 years old. Otherwise they were liable to become misshapen. The Chairman advocated regular feeding. The stables should be kept clean and dry and should be spacious enough to allow the horses to lie down. Mr. A. M. Wilson thought all corn should be crushed before being fed to horses. Members generally agreed with the writer of the paper.

MITCHELL.

November 1st.—Present: 16 members and seven visitors.

Hay-Cutting.—In a short paper on this subject, Mr. D. Green said wheaten hay for feeding as chaff should be cut when the straw was purple at the nodes; hay for long feeding was better cut earlier, say a week after the blossom had fallen. Oats should be left until they were well advanced; they should be chaffed, otherwise the horses would only eat the heads.

Destruction of Rabbits.—Mr. D. Green also read a short paper. He recommended raspberry jam and strychnine for poisoning rabbits, the baits being laid during the months of November, December, and January. Several members thought the poisoning could be continued until May, or when the first rains fell. Mr. Vigars favored digging out the pest. Phosphorus and pollard constituted the best poison for rabbits in rocky country. Mr. Mayhew mentioned that oats dipped in a solution of strychnine and sugar had been used with considerable success. Mr. Jericho recommended trapping.

ROBERTS AND VERRAN.

November 11th.—Present: 12 members and one visitor.

Harvester v. Stripper.—Mr. F. Masters, in a paper on this subject, said the harvester was the best means of dealing with the wheat crop, especially for the small farmer. Less damage resulted to the grain, and there was less chance of loss and waste when it was bagged immediately. This machine was also capable of doing the work much more cheaply than the stripper and winnower, less labor was required, and the work was much more pleasant.

Mr. R. Johnson also read a paper. For the farmer commencing in new mallee country, he said, the stripper was the best machine. The life of the stripper was much longer, there was less trouble with breakages, and the sample turned out was better. There was difficulty in securing labor capable of handling the harvester. As the wheat was left in heaps in the paddocks green leaves and rubbish which might have been collected would have a chance to dry, they would then be more easily removed with the chaff. Mr. W. Sharman, who was using both a harvester and a stripper at the present time, favored the latter, as it enabled him to get the crop off more quickly. The ground was too rough, and the crops rather too light for the profitable use of the harvester.

MANGALO, November 12th—Annual Meeting.—The meeting took the nature of a social gathering. The Hon. Secretary presented his annual report, which showed that the Branch was in a flourishing condition and had accomplished good work during the year
